# INDEX.

Abdominal Hysterectomy without a Pedicle, with report of ten Consecutive Cases, Rubus B. Hall., M. D., Cincinnati Ohio, 100.
Pain Following Typhoid Fever, 282.
Surgery by Untrained Operators, with Deficient Appliances, J. McFaddon Easton, M. D., Atlanta, Pa , 360.
Abnormal development of the Teeth Forming Tumors of the Jaw, 145.
Abortive treatment of Buboes, 772.
Treatment of Gonorrhœa, 772.
Absence of Gentials; Vicarious Epistaxis, 622.
Of the Liver, G. Frank Lydston M. D., Chicago Ill., 849.
Actinomycosis cured by Potassium Iodide, 995.
A Case of Senile Gangrene Treated by Amputation G. W. H. Kemper, M. D., Muncie, Indiana, 638.
A Committee on Drink, 912.
Acquired Syphilis in Childhood, 882.
Action of Bicarbonate of Sodium on Digestion, 878.
Of Pilocarpine on Bodily Temperatures, 700.
Acute Intestinal Obstruction Treated by Laparotomy, 52.
Ulcerative Endocarditis Due to Bacillus of Diphtheria, 69.
Administration of Milk by Accurate Dosage, 956,
Additional Note on treatment of Exophthalmic Goiter, 63.
Address in Medicine, S. W. Latta, M. D., Philadelphia, 446.
In Obstetrics, Thos. D. Dunn, M. D., West Chester, 449.
Adenoids, a Factor in Aural Affections, 795.
A Departure in the Treatment of Bright's Disease, W. H. Walling, M. D., Philadelphia, 749.
Administration of Anæsthetics, 700.
Advantages of a Physician Dispensing his own Medicine, 660.
Affections of the Labyrinthine Capsule a Frequent Cause of Deafness, 788.
A Medical Objection to Dancing, George L. Beardsley, A. M., M. D., Birmingham, Conn., 479.
American Inebriate Asylums, 420, 562.
Amputation for Diabetic Gangrene. 919.
Of Leg. 288.
Anæsthesia, Wm. H. Barr, Wilmington, Del., 110.
Anæsthetics, George Foy, Dublin, 216.
Analysis of one hundred and twenty-five Cases of Hernia, 58.
Announcement—College of Physicians of Philadelphia, 385.
Anthrax, 693.
Bacilli in Mud at Bottom of Well, 761.
Antidote for Carbolic Acid, 384.
Antiseptic Intra-Pleural Infection, 427.
Treatment of Burns in Children, 881.
Treatment of Ozena, 620.
An Unusual Case of Hemorrhage of the Uterus, Clara T. Dercum, M. D., Philadelphia, 637.
A Peaceable Race, 455.
Appendicitis, 288, 771.
And its Complications from a Surgical Standpoint, 187, 458.
What it is and what it is not from a Surgical Standpoint, 55.
What it is and what it is not. from a Surgical Standpoint, Joseph Hoffman, M. D., Philadelphia, 303.
Arsenic Internally in Cancer, 866.
Arsenical Neuritis, 154.
Artificial Delivery in Copenhagen, 582.
Diamonds, 190.
Opening of Pulmonary Cavities, 56.
Asthma, 995.
Ascites—its Treament from a Gynecological Standpoint, 909.
A Serious Gun-Shot Wound of the Thigh Without Hemorrhage, A. O. Stimpson, M. D., C. M. Thompson, Pa., 719.
Asiatic Cholera in England, 576.
Association of Diseases and Morbid Processes, 64.
A Table of Food Values, 655.
A Treatment for Fistula in ano Without a Cutting Operation, T. J. Bennett, M. D., Austin, Texas, 364.
Aural Vertigo, Meniere's Disease.
Auscultation in Fractures, 520.
A Year's Work in Minor Gynecological Surgery, Charles P. Noble, M. D., 824.

Bacilli and Nitric Acid, 634.
Bacillus of Diphtheria (Klebs' Loeffler Bacillus), 68.
Bacteria in the Soil at different Depths, 374.
Bacteriology and Country Hygiene, K. S. Howlett, M. D., Bigbyville, Tenn., 7.
Bathing After Exercise, 580.
Bi-Cornate Uterus; Placenta Previa; Cæsarean Section, William Varian, M. D., Titusville, Pa., 478.
Biographical Sketch of the Late Isaac Kerlin, M. D., Laurence Turnbull, M. D., Ph. D., Philadelphia, 829.
Blood Changes in Syphilis, 309.
Bloodless Amputation at Hip Joint, 77.
Blood-Letting as a Therapeutic Agent in the Treatment of Diseases, J. S. Dukate, M. D., 585.
Blood Pressure, Wm. Bailey, M. D., Louisville, Ky., 277.
Blood Pressure, 331.

BOOK REVIEWS.
A Chapter on Cholera for Lay Readers: Walter Vought, Ph. B., M. D., 990.
A Manual for Boards of Health and Health Officers, Lewis Balch, M. D., Ph. D., 462.
An American Text Book of Surgery for Practitioners and Students, 461.
An Introduction to Study of Diseases of the Skin, H. H. Pye-Smith, M. D., F. R. S., F. R. C. P., 268.
A Standard Dictionary of English Language, 35.
A System of Genito-Urinary Diseases, Syphilology, and Dermatology, 842.
A Text-book of the Theory and Practice of Medicine, By American Teachers, 731.
Cholera, Dr. G. Archie Stockwell, F. Z. S., 990.
Clinical Lectures on Abdominal Hernia, Wm. H. Bennett, T. R. C. S., 731.
Cosmopolitan for November, 732.
Diseases of the Nervous System, Dr. Ludwig Flint, 35.
Diseases of the Rectum and Arms, Charles B. Kelsey, A. M., M. D., 732.
Duane's Students Dictionary of Medicine, Alexander Duane, M. D.
Dungleson's New Pronouncing Medical Dictionary, 384.

Electro-Therapeutics of Neurasthenia, W. R. Robinson, M. D., 990.
Hospitals and Asylums of the World, H. C. Burdett, 383.
Les Troubles du Language Chez Les Alienes, J. Seglas, 952.
Manual of Bacteriology for Practitioners, Dr. S. L. Schenk, 951.
Materia Medica and Therapeutics, John V. Shoemaker, 2 vols., 36.
Recent Developments in Massage, Douglass Graham, M. D., 990.
Review of Reviews, 384.
Sharp & Dohme's Price List for 1893, 384.
Somsino, P. Sviluppo, ciclo vitale e ospite intermedio della Bilharzia hæmatobia, 843.
Surgery and Surgical Anatomy of the Ear, Albert H. Tuttle, M. D., 35.
System of Diseases of the Ear, Nose, and Throat, 732.
Text Book of Normal Histology, George A. Piersol, M. D., 951.
The Health Resorts of Europe, Thomas Linn, M. D., 731.
The Medical News Visiting List for 1894, 842.
The Ready-Reference Hand-Book of Diseases of the Skin, George Thomas Jackson, M. D.
The Theory and Practice of Medicine Prepared for Students and Practitioners, James J. Whittaker, M. D., L. L. D., 804.
Various Forms of Hysterical or Functional Paralysis, H. Bastion, Charleston, M. A., M. D., F. R. S., 268.

Brain Surgery, 56.
Brief Clinical Memoranda, 63.
Bright's Disease, John M. Batten, M. D., Pittsburg, 601.
Bromide of Potassium for Invagination, Harvey Vannetta, M. D., Seal, Ohio, 294.
Bromoform in Whooping Cough, 868.
Broncho-Pneumonia, J. C. H. Lawrence, M. D., Green Bay, Wis., 522.

Caffeine Chloral, 228.
Calomel in Gout, 619.
Soap in the Treatment of Syphilis, 660.
Cancer of Rectum, 373.
Carbolic Acid used in Full Strength in Surgery, 860.
Care of Catheters, 772.
Of Upper Air Passages in Treatment of Syphilis, 176.
Case of Puerperal Eclampsia, 948.
Cause Which Determines Sex, 148.
Cerebro Spinal Architecture as a Factor in the Diagnosis of Nervous Diseases, John Punton, M. D, Kansas City Mo., 1
Spinal Meningitis, 540.
Chancre of the Mouth, 910.
Changes and Degenerations in Naevi, 919.
In the Cardial Ganglia in Acute and Sub-Acute Endocarditis, 308.
Chemical Antidote for Cyanide of Potash, 800.
Chlorate of Soda in Cancer of the Stomach, 836.
Chloride of Ammonia in Cystitis, 800.
Of Gold and Sodium in Bright's Disease, 692.
Of Iron in Diphtheria, 153.
Chloroform as a Tape Worm Remedy, 620.
Anæsthesia and its Administration. Part Second, 207.
Mortality in Australia, 879,
Cholera, Earnest Hart, London, 45.
And its Management in Hull, England, 682.
Bacilli in Dust, 661.
Infantum and its Treatment, Manuel Septien, M. D., Quevetaro Mexico, 671.
Its Prevention and Treatment, 378.
Cholecystotomy, 257.
Chronic Diarrhœa, Insomnia, Attempted relief by Hynotism, Erythema, Nodosum, 254.
Glanders Terminating Fatally in Acute Exacerbation, 534.
Cicatricial Stricture of Pylorous, Pyloroplasty, A. M. Cartledge, M. D., Louisville, Ky., 745.
Classification of Arteritis, 186.
Cleft of the Hard and Soft Palates, J. Ewing Mears, M. D., Philadelphia, 966.
Clinical Course, Diagnosis, and Structure of Cancers, 955.
Clinical and Etiological Observations of Psoriasis, 761.
Aspects of Pneumonia in Children, Henry E. Tuley, M. D., Louisville, Ky., 361.
Observations in Philadelphia, W. H. Link, M. D., Petersburg, Ind., 97.
Regions of the Abdomen, 828.
Report of a Case of Hepatic Abscess, A. J. Block, M. D., New Orleans, La., 371.
Thermometers, 459.
Cocaine and the Milk Secretion, 770.
In General Medicine, 220.
Cold Abscess of Foot; Underlying Tuberculosis of Tarsus; Amputation of Leg; Tubercular Arthritis of Knee; Amputation of Thigh, Rosewell Park, A. M., M. D., 317.
Collection and Disposition of Animal and Vegetable Waste in Milwaukee, 681.
Complications of Vaccination, 956.
Combined Effects of Morphine and Sulphonal, 466.
Complete Reunion of Severed Fingers, 582.
Compound Dislocation of Left Ankle and Fracture of the Internal Malleolus—Astragalus and Internal MallelousExcised, Charles B. Williams, A. B., M. D., Philadelphia, 131.
Fracture of the Skull, 60.
Conception on the Fourth Day of Child-bed, 78.
Condition of Spinal Ganglia in Tabes Dorsalis, 153.
Conservative Operation of the Ovaries, Tubes and Uterus, 543.
Considerations Bearing on Treatment of Pneumonia. 51.
Constipation, 134.
Consumption of the Lungs is not to be Compared with Leprosy, Samuel G. Dixon, M. D., Philadelphia, 758.
Continued Report—Tumor in Epigastric Region, 289.
Contra-Indications and Indications for Sea-bathing Children, 980.
Continued Report, 415.
Contribution to the History of the Discovery of Modern Surgical Anæsthesia, with New Data Relative to the Work of Dr. Crawford W. Long, Luther B. Grandy, M. D., Atlanta, Ga., 646.
To the Operative Treatment of Congenital Hip-Joint Dislocations, 530.
To Pathology of Experimental Diphtheria with Special Reference to Appearance of Secondary Foci in Internal Organs, 69.
To the Statistics of Renal Surgery, Dr. James Israel, 515.
To the Study of Yellow Fever From a Medico-Geographical and Prophylactic Point of View in the Mexican Republic, Edwards Liceage, M. D., Mexico, 701.
Convulsions, 840,
Correction of Syphilitic Deformity of Nose; Syphilitic Stenosis of Larynx; Amputation of Leg on Account of Compound Dislocation of Ankle; Torticollis Collar; Removal of Breast for Cancer, Roswell Park, A. M., M. D., Buffalo, N. Y., 512.
Coughs in Children, W. Henry Price, B. A., M. D., Philadelphia, 780.
Craniectomy, 883.
In Idiots, 772.
Craniometric Measurement in Relation to Aural Topographic Anatomy, 796.
Creolin a Mixture of Carbolic Acid and Resin Soap, 75
Creosate in Latent Tuberculosis, 869.

Crying in Children, 349.
Crystalline a Substitute for Collodion, 836.
Cystitis, 838.

Dangers and Avoidance of Ergot in Obstetrics, 922,
In Antiseptic Midwifery, 261.
Of Vaginal Pessaries, 115.
Deaths from Anæsthetics in Germany, 879.
From Salol, 770.
Decline in Consumption of Liquor, 769.
Demonstration of Gastrodiaphany, 65.
Dermoid Cyst of the Tongue, 293.
Destruction of Microbes by Infusoria, 938.
Detection and Significance of Carbo-Hydrates in the Urine, 64.
Diabetes, 919.
And Cirrhosis of the Liver, 581.
In a Baby, 919.
Insipidis, F. P. Butler, M. D., Marshalltown, Iowa, 14.
Diagnosis and Treatment of Empyema, O. C. Baker, M. D., Brandon, Vt., 784.
In Diphtheritic Angina, 839.
Of Inebriety from Apoplexy, 699.
In Abdominal Tumors; Prolapsus Uteri, E. E. Montgomery, M. D., 741.
Of Apoplexy, 76.
Of Epilepsy by the Urine, 655.
Diarrhœa Caused by Infusoria, 615.
In Children, J. D, Weaver, Norristown Pa., 405.
Diffuse Gangrene of Left Lung, 995.
Differential Diagnosis and Treatment of Chronic Ear Disease, 344.
Diagnosis of the Various Forms of Convulsions in Young Children, 114.
Digital Compression in the Vomiting of Anæsthesia, 231.
Diphtheria and Scarlet Fever at the Boston City Hospital, 1001.
Diphtheria, 64.
T. J., Happel; A. M., M. D., 79.
W. H. Burr M. D. Wilmington, Del., 853.
Discharge of Ascarides by the Umbilicus, 809.
Of Pus at the Navel following an attack of Typhoid Fever, 281,
Discussion of Dr. Adams' paper, 485.
Of Paper Surgery of Tubal Pregnancy, W. A. O. and G., 525.
Disease Due to Streptococci, 691.
In the Sigmoid Flexure, 23.
Of the Spleen and their Importance, 345.
Probably Caused by Flies, 261.
Disorders of Nervous System Associated with the Change of life, 766.
Disposal of Garbage and Waste of Columbian Exposition, 681.
Disputed Points in Hysterectomy, Joseph Price, A. M. M. D., Philadelphia Pa., 11.
Double Empyema, 581.
Hydrocele, 750.
Lesion of the Brain; Cerebral Cyst and Cerebellar Tumors, 560.
Pyosalpinx, 424.
Duboisine Sulphate as a Sedative, 799.
Dyspepsia as a Nervous Disease, 555.

Early Aspiration in Acute Pleuritis. 64.
Management of Club-foot, 771.
Removal of Tubercular Foci of Bone. B. Merill Rickets, M. D., Cincinnati, O., 200.
Treatment of the Insane, 338.
Ectopic Gestation in Both Tubes, 424.

EDITORIAL.

For Obstinate Vomiting of Pregnancy, 596.
Foreign Substance in the Ear for Thirty Years, C. C. Moore, M. D., Philadelphia, 175.

FORMULÆ.

Absorption Required, 150.
Acute Bronchitis, 870.
Acute Coryza, 72
Acne, 150, 298, 871.
Acute Rheumatism, 223, 771.
Alopecia Circumscripta, 265.
An Alkaline Tincture, 340.
An Epilatory in Skin Diseases, 692.
Antiseptic Varnish, 920.
Aristol in Hemorrhoids, 132.
Atrophic Rhinitis, 226.
Aqua Picis in Cholera, 226.
Bee Stings, 868.
Bites of Insects, 226.
Bromidism, 150.
Brown Leather Polish, 150.
Burns, 267.
Carbuncle, 29
Chloroform for Tape-worm, 880.
Chronic Bronchitis and Emphysema, 226.
Cocktail Bitters, 316.
Constipation in Dyspeptics, 801.
Constitutional Syphilis, 226.
Cramps of Legs in Pregnant Women, 305.
Cutaneous Diseases, 226.
Deodorizer for Iodoform, 150.
Diarrhœa 29.
Diphtheria, 868.
Dysmenorrhœa, 836.
Dyspnœa of Acute Phthisis, 838.
Eczema of Ear and External Auditory Canal, 9.
Of Vulva, 150.
Embalming, 151.
Enlarged Tonsils, 226.
Flatulent Dyspepsia, 29.
Formulæ for Antiseptic Treatment of Boils and Carbuncles. 694.
Gonorrhœa, 105.
Good Alterative, 305
Hardening and Coloring Plaster of Paris Casts, 191.
Hemoptysis, 800.
Herpes Zoster, 226.
Hyperidrosis, 150.
Hypodemic Injections of Iron in Anæmia, 218.
Hysteria, 800.
Inebriety, 882.
Interigo, 305.
Itching After Eruptive Diseases, 868.
Label Paste, 185.
Laryngeal Phthisis, 185.
Leucorrhœa, 694.
Liniment for Neuralgia, 29.
Liquid Spice Plaster, 150.
Local Anæsthesia, 185.
Syphilides of the Scalp, 218.
Migraine, 199, 868.
Malignant Lymphoma, 867.
Naso-Pharnygeal Catarrh of Nurslings, 179.
Naphthaline in Taste Worm, 802.
Nervine Tonic in Pill Form, 345.
Nocturnal Sweats of Consumption, 226.
Night Sweats of Pulmonary Tuberculosis, 29.

**Pharmaceutical Products of the Farbenfabriken vorm Friedr Bayer & Co.**

**Phenacetine-Bayer**

ANTIPYRETIC and ANALGESIC; Prompt, safe and effective in Fever, Influenza, Rheumatism, Neuralgia, Pneumonia, Cephalalgia and all forms of pain.

Phenacetine is given in doses of 2½ to 10 grains, 3 or 4 times daily. It does not depress the heart.

Phenacetine is supplied in ounces, also in tablets and pills, alone and with Salophen, Sulfonal, etc.

**Sulfonal-Bayer**

HYPNOTIC and SEDATIVE; Indicated in all the Insomnias including those of insanity and the Neuroses; Causes no nervous or gastric disturbances. Must be given as directed.

The dose of Sulfonal varies from 15 to 45 grains; It should be given an hour or two before bedtime.

Sulfonal is supplied in ounces, tablets and pills; also in tablets in combination with Phenacetine.

*Other Farbenfabriken Products:*

**Salophen, Trional, Aristol, Losophan, Piperazine-Bayer, Europhen.**

*New descriptive Pamphlets on these Preparations mailed by*

**W. H. Schieffelin & Co., New York.**

# SVAPNIA

OR

## PURIFIED OPIUM

**FOR PHYSICIANS USE ONLY.**

**Contains the Anodyne and Soporific Alkaloids, Codeia, Narceia and Morphia.**

**Excludes the Poisonous and Convulsive Alkaloids, Thebaine, Narcotine and Papaverine.**

SVAPNIA has been in steadily increasing use for over twenty years, and whenever used has given great satisfaction.

To PHYSICIANS OF REPUTE, not already acquainted with its merits, samples will be mailed on application.

SVAPNIA is made to conform to a uniform standard of Opium of Ten per cent. Morphia strength.

JOHN FARR, Manufacturing Chemist, New York.

C. N. CRITTENTON, Gen'l Agent, 115 Fulton St., N. Y

To whom all orders for samples must be addressed.

SVAPNIA IS FOR SALE BY DRUGGISTS GENERALLY.

---

## NO WAX

Is used in our **Hollow Suppositories.** Made from purest **Butter of Cocoa only,** which **melts** at the temperature of the **body.** Can be filled with any medicine. Anal, Nasal, Urethral, Cystic, Vaginal, and Intra-Uterine sizes.

Also, Ricord's Solid Suppositories for Gonorrhœa, and Nelaton's Solid Suppositories for Constipation and Piles. Samples sent Free on application and mention of this paper.

HALL & RUCKEL,

218 Greenwich St. New York City.

---

## MARLIN SAFETY

## REPEATING RIFLES

Made in all styles and sizes. Lightest, strongest, easiest working, safest, simplest, most accurate, most compact, and most modern. For sale by all dealers in arms. Catalogues mailed free by

**The Marlin Fire Arms Co.,**

NEW HAVEN, CONN., U. S. A.

### CEREBRO-SPINAL ARCHITECTURE AS A FACTOR IN THE DIAGNOSIS OF NERVOUS DISEASES.

JOHN PUNTON, M. D.,* Kansas City, Mo.

By virtue of his mysterious and complex nature man has attracted the attention of the brightest intellects of every department of learning from time immemorial, and this attraction is even greater to-day than ever before.

To the searcher after truth he has ever proven himself an enigma. Considered from whatever standpoint, man has furnished more riddles and problems to the square inch than any other creature we know anything about; certainly no other object has been the subject of more severe and critical analysis than he, yet to-day we are all willing to admit the fact that there is still much concerning man that is still unknown to us.

While this may all be true, nevertheless it is a very gratifying fact for us to know that each and every century has furnished a greater or less number of investigators in the various departments of medicine, whose combined labors have solved many of the more difficult problems concerning his physical nature, and rendered possible the study of man on a scientific basis.

In an impartial investigation, therefore, sound method requires that we take into consideration all the phenomena presented, each in its completeness and natural relations, and an estimate of their full value given in accordance with their relative weight and bearing on the problems at issue. By the application of such methods in the study and order of nature, we soon discover the elements of a plan or system which shows progress in the unfolding of its parts from the lower and more simple forms of life to the higher and more complex. Each department of nature is thus seen to become higher and higher through the addition to itself of something in organization and endowment which the next below it does not seem to manifest or possess, but which have definitely been demonstrated to reach the very height of its power and perfection in the human brain convolutions.

In no other department of medicine is this law of evolution more beautifully illustrated or carefully observed than that which has been found to exist in the development of the central nervous system.

The very fineness of architecture and delicacy of structure has rendered its study beyond human skill until quite a recent period, hence the true nature of its anatomy and physiology all along the ages has been very imperfectly understood. The force and gravity of this lack of knowledge is very apparent when we remember that one of the fundamental principles of medicine declares that to understand pathological we must first possess a thorough knowledge of physiological processes.

*Professor of Nervous and Mental Diseases, University Medical College, Kansas City, Missouri; Special Lecturer Western Dental College; Neurologist to All Saints Hospital, etc.

The history of the progress of medicine also shows that just in proportion to our knowledge of the anatomy and physiology of any given part, does our knowledge of the symptomatology of its disease advance. The great aim, therefore, of scientific investigation, as Dr. Starr says, is to associate symptoms with lesions, and this has been done to a remarkable degree of late, chiefly along the lines of anatomy and physiology, through the instrumentality of the microscope.

In tracing the general outline of the history of the progress of medical science, it seems to me that it naturally divides itself into two great epochs, the first dating as far back as the days of Vesalius, the worthy founder of anatomical science in the year 1514, A. D., and the second from the introduction of the microscope into medicine by Leuwenhœck, until the present time.

These two great epochs stand out in special salience and present a marked contrast in the steepness of the rise of knowledge they present when duly compared.

In addition to this, they also represent the two great departments of study which have furnished all that is known concerning man's physical nature. These may be termed: I. *ma*croscopical; II. *mi*croscopical study. In these are included all the varied lines of scientific research; and all the various discoveries, from whatever source, belong to one or the other of these periods.

In this connection it must be remembered that the student of medicine has necessarily been forced to depend upon the different means and methods placed at his disposal by the arts and sciences of his own epoch, hence the smallest technical discovery frequently became of inestimable value. Considering the crude and limited means and methods of investigation belonging to the first epoch, the labors of such men as Vesalius, Eustachius, Fallopius, Pachioni, Harvey, Willis, Vieussens, Meckel, Scarpa, and many others whose names are immortalized in anatomical nomenclature, cannot be over-estimated and their discoveries testify as to their greatness and earnestness of purpose. Nevertheless it is the *microscopical* epoch to which our greatest advance belongs, and it is this we are compelled to recognize as furnishing the most marvellous and brilliant results, as well as the most practical knowledge. It is to certain consequences therefore, concerning this microscopical period and notably those of the past few years, that I desire to call attention at this time, consequences that seem to me to be of the utmost importance to the general practitioner, as well as to the neurologist in their daily practice.

The marvellous extent of the changes wrought cannot be realized by all the members of our profession, and for obvious reasons. Those of you who studied medicine before the change took place have been unable to follow the new development of knowledge on account of the exigencies of general practice with its ever increasing demand on your time and energies, for the successive steps have followed each other with a rapidity almost bewildering. Then again the large number of practitioners who studied medicine more recently and during the time in which these changes were in actual progress, but were yet subject to doubt, necessarily learned fragments of the new but large quantities of the old doctrines concerning the genesis of nervous diseases, thus acquiring a mixture which to-day we know to be quite incompatible and consequently harmful.

Before our present perfected knowledge, the pathology of nervous diseases was usually inferred from analogy, but to-day we know that the analogy was false and the malady itself quite different from that which was then supposed to exist. The vast increase of our knowledge of the anatomy and physiology of the nervous system, which is so salient a feature of recent progress, and the application of this to disease, has been found to be most useful in the correction of such erroneous inference and the displacement of the work of fancy by ascertained positive fact.

By it also our nomenclature has been greatly enlarged, our classification of diseases wonderfully improved and modified and our means and methods of diagnosis thereby rendered more perfect and reliable.

The application of the perfected microscope to pathology immediately increased the range of so-called organic diseases. The term organic being used to designate those diseases in which the lesion is visible and, as visibility is only a relative term depending on the means of vision, it is easy to understand the great changes which have

been wrought in this department alone. For instance, prior to the discovery of Turck ("That a break in the conductivity of certain nerve fibres in the spinal cord always led to a degenerative process which spread upwards or downwards according to its seat") our knowledge of the pathology of spinal diseases was very imperfect, hence a correct diagnosis was impossible; but the application of this fact and its further elaboration furnished us with that most valuable pathological classification of diseases of the spinal cord into systemic and non-systemic diseases.

In view of all the remarkable advances which have been made of late in this department of medicine, is it any wonder that those only familiar with the old, should be lost in the mazes of the new? All important, therefore, is the knowledge which recent investigation affords concerning cerebro-spinal architecture and its use as a factor in the diagnosis of nervous diseases.

The wonderful perfection which has been attained of late in elucidating the complex mechanism of the nervous system may be said to largely depend upon three methods of research, viz., I. The degenerative method discovered by Turck, in 1850; II. The atrophic method of Von Gudden, in 1870; III. The developmental method of Flechsig, in 1877.

It was the further elaboration of these that gave us the present perfected knowledge of cerebro-spinal architecture, and rendered it most valuable as an aid in diagnosis. In their utilization, the most remarkable results have been accomplished, and still in process of enlargement.

It would be impossible for me to give in detail the structure and functions of all the various parts which constitute cerebro-spinal architecture, so that at best I can give but a hurried glance of some of the more important, yet I will endeavor to review briefly some of the principal facts as demonstrated by the more modern researches in America, England, France and Germany, and those which are now generally conceded and accepted as proven.

The department of medicine that relates to neurology is based on physiological principles, and recognizes the nervous system, with its various appendages and correlating energies, to be the supreme controlling force in man. Its functions taken collectively, associate the different parts of the body in such a manner that a stimulus applied to one organ excites to action another. It is composed of a series of connected central organs called collectively: I. the cerebro-spinal centre, or axis; II. ganglia; III. nerves; IV. certain modifications of the peripheral terminations of nerves which form the organs of the external senses.

It is divided into two great systems, I. Cerebro-Spinal; II. Sympathetic.

The first includes the brain, spinal cord, cranial nerves, spinal nerves, and is in direct connection with the cerebral centers.

The sympathetic is not in direct connection with the cerebral centers, but is so indirectly, by means of numerous branches which go to and come from it. It essentially consists of a double chain of ganglia.

The spinal cord is a long rod or mass of nervous tissue, enclosed in a bony canal formed by the bones of the spine. It consists of white and gray nervous tissue, the white being most external and capable of division into various tracts or columns, which are connected centrally with the brain. It gives off at regular intervals the spinal nerves in successive series, which are distributed to the various muscles.

The white substance is made up of at least nine tracts of fibres which differ in function according to its situation. It is usually divided into three primary columns, viz: (*a*) anterior; (*b*) lateral, and (*c*) posterior. (*a*) The anterior is motor in function; (*b*) the lateral column is much more complicated and has a mixed function containing both motor and sensory fibres.

(*c*) The posterior columns of the cord present two well defined tracts known as the column of Goll and column of Burdach, and these are said to be essentially sensory in function. Now the study of the course and distribution of these different tracts and their special uses constitute one of the most difficult problems in neurology, for it is by these that impressions from without are conveyed to the brain and transformed into other impulses. One of them is said to convey the sensations of pain, another those of touch, a third varying degrees of temperature, a fourth that of muscular sense; while still others represent the so-called motor tract, which for the most part

crosses at the medulla, while certain fibres, known as the column of Turck, ascend to the brain on the same side.

The gray matter of the spinal cord is made up of several distinct groups of cells which are said to be the residence of special centers which govern different functions of the body, the principal ones being that of reflex action, trophic and nutritive powers, as well as the source of innervation of the sympathetic system.

As the gross anatomical features of the brain are already familiar to you, I shall merely refer to them incidentally, but speak more especially of these parts the knowledge of which, in my judgment, is more requisite in the diagnosis of nervous diseases.

The brain consists of a variety of nerve centers arranged in layers or masses, connected with each other as well as the spinal cord and other organs by means of various tracts of nerve fibres which differ in function and structure. The most external layer consists of gray matter and constitutes the cerebral cortex.

Now the cortex of the brain is the seat of all conscious mental action. It is therefore the receptacle of all impressions made upon the organs of sight, hearing, touch, taste and smell. Here and here only do such impressions become transformed into conscious appreciation of external objects. From it also proceed all the motor fibres distributed to the voluntary muscles, under the name of the motor tract, as well as the sensory fibres which gives rise to psychical perception of external impressions.

Now certain portions or areas of this cerebral cortex preside over different distinct functions or actions of the body; indeed it may truly be said that every part of the body is represented in it. As Dr. Ramsey well says: "By facts at our command to-day we know that one portion is limited to vital processes, hence its destruction causes instant death;" another part presides over the various movements of the body, hence paralysis of motion results from injuries to this area; a third enables us to appreciate the sense of touch, another of pain, another of temperature, and disturbances of these functions will be apparent when these regions are diseased. Another portion presides over the sense of sight, hence disturbances of vision, or even blindness, may follow injury or disease of this part. In the same manner hearing and smelling are governed, and when a combined action of all these parts are demanded, as in the exercise of reason, will, or self control, the knowledge gained by these means can be contrasted, and their specific functions correlated in such a manner as to meet the exigency of the case."

From this, then, we learn that the external surface of the brain can be mapped out into a series of definite areas or regions, and say positively that this or that one controls or presides over this or that particular function of the body. By a thorough knowledge of these special areas, the skilled physician can determine by the symptoms which their derangement produces, the exact situation, extent and nature of the lesion.

So positive, gentlemen, is the information thus afforded to-day, that surgical operations are now performed daily for their relief, whereas a few years ago such a proceeding was considered impossible.

I will now endeavor to demonstrate the various areas or regions referred to, together with their special functions. For convenience I have divided the brain into four parts, or lobes, viz.: I. Frontal; II. Parietal; III. Occipital; IV. Temporal. The names, as you will observe, correspond to the names of the bones of the skull which encase them. They are separated from each other by three important fissures, viz.: I. Sylvius; II. Rolando; III. Parieto-Occipito.

### I.—FRONTAL LOBE.

The first frontal lobe represents four principal convolutions which are separated by fissures, the largest one being termed the precentral, and divides this region into two parts, an anterior and posterior.

That part which lies in front consists of three convolutions, first, second and third frontal; it is sometimes termed the prefrontal lobe. In these are supposed to reside the centers which control the higher mental faculties such as judgement, reason, will, self-control, etc. Any injury to this part is liable to cause a disturbance of these faculties. At the lower portion of the third frontal reside the centers which Broca long ago designated as the speech area, or the seat of language. Injury or destruction of this may cause an impairment of speech, or even complete Aphasia.

The posterior portion of the frontal lobe constitutes a part of the motor area, and is known as the ascending frontal.

II.—PARIETAL LOBE.

This lobe is also made up of four principal convolutions named, Ascending Parietal, Superior Parietal, Supra-Marginal, and Angular. These are separated from each other by small fissures, and divided into two portions by a larger fissure termed the fissure of Rolando. This is the important landmark for all surgical operations in and around the motor area.

That portion situated in front of the fissure, together with the ascending frontal and a portion of the superior parietal termed the Paracentral lobule, constitutes the whole of the motor area. In this resides all the centers which govern the voluntary movements of the body. For convenience it may be divided into three parts: An (*a*) upper, (*b*) middle, (*c*) lower. The first governs the movements of the legs; the middle, the arms; the lower, the lips and tongue. Any injury to these may cause corresponding paralysis to the parts supplied. The remaining portion of the parietal lobe not specially belonging to the motor area, and separated from it posteriorily by a large fissure termed the intra-parietal, represents the regions which are probably the seat of conscious perceptions of touch, pain and temperature, and consequently may be styled a sensory area.

III.—THE OCCIPITAL LOBE.

The occipital lobe is made up of three convolutions which preside over the sense of sight, and the recognition of familiar objects by the eyes depends entirely upon the integrity and activity of the cells of this portion of the brain. Any injury to this may cause disturbance of vision and destruction of the cuneus may produce blindness.

IV.—TEMPORAL LOBE.

Finally, the temporal lobe is the region or seat of the centers which enable us to consciously appreciate sounds, odors or taste, hence it represents the centers of the special senses of hearing, smelling and taste. Like the occipital, it is composed of three convolutions separated from each other by small fissures.

All these various centers are thus seen to have their residence in the cerebral cortex. This cortex forms a vault or dome arching the large mass of white substance beneath and known technically as the centrum ovale.

Proceeding in every direction from these centers are the nerve fibres which converge from all parts of the cortex to form the corona radiata and centrum ovale. Starr says that these fibres may be arranged in three sets, viz.: I. Association fibres which connect the cells of different areas in the same hemisphere.

II. Commisural fibres which connect homologous parts of the opposite hemispheres and therefore cross the median line.

III. The projection or peduncular fibres which connect the different areas of the cortex with other parts of the nervous system lying below it. They converge from all parts of the cortex and gathering together at the upper level of the basal ganglia either terminate in the optic thalamus or pass between the basal ganglia to other parts of the brain and spinal cord. The fibres terminating in the optic thalamus constitute the visual and auditory tracts, while the rest of the fibres pass on at once to the internal capsule where they form a series of different tracts with special functions. From before backwards they are as follows:

I. The speech tract, conveying speech impulses to the pons and medulla.

II. The face tract, conveying facial motor impulses to the pons where the nucleus of the seventh nerve resides.

III. The arm tract, destined to the arm center in the cord.

IV. The leg tract, transmitting leg impulses to the leg centers in the cord.

V. The fibres conveying impulses to the muscles of the trunk.

Hence, it appears that the centers for the legs, which are highest in the cortex, become lowest in the capsule, while the face fibres, which are lowest in the cortex, become highest in the capsule; but the arm fibres are situated between the two at the cortex as well as the capsule.

These various tracts of fibres constitute the motor tract whose course through the anterior two-thirds of the posterior portion of the internal capsule is probably familiar to all of you, and from this point passing to form the middle third of the crus cerebri or pes peduncle, thence to the pons where the facial fibres decussate to

opposite sides to end in their respective nuclei, while the balance of the fibres are continued by way of the pyramids of the medulla, where they for the most part decussate to form the crossed pyramidal tract of the cord while a few are continued down the cord, on the same side as far as the mid-dorsal region, under the name of the column of Turck. All of these fibres which are continued from the brain to the spinal cord terminate in the large cells found in the anterior cornua of the gray matter where they again take origin to be distributed to the voluntary muscles of the body. Besides the motor set of projection fibres there is still another set known as the sensory tract. It lies just posterior to the motor tract and passes inwards into the parietal convolutions to the capsule, where, in general terms, it may be said to take a similar course to that of the motor. It is made up of fibres which convey the sensations of touch, pain, temperature and muscular sense; hence any lesion in any part of its course causes corresponding disturbances of those functions.

Thus the fibres which constitute the internal capsule possess, as Dr. Ranney says, greater interest than many others, both from a physiological as well an anatomical standpoint.

Late researches have shown that it contains a successive series of tracts or bundles, the functions of some of which are definitely known while others are not yet well determined. Taken collectively they may be arranged as follows:

1. That part of the internal capsule designated as the caudo lenticular portion, which lies anterior to the knee, is composed of fibres whose functions are imperfectly understood. They seem, however, to pass chiefly to the cortex of the frontal lobes and thus they would appear to be associated with the higher mental faculties.

2 The functions of the majority of the tracts of fibres, however, found in the thalamus and lenticular portion of the internal capsule are definitely known and serve as valuable clinical guides to the localization of cerebral lesions which directly involve or create pressure upon them. They are as follows:

*A.* In the region of the knee are found the motor fibres of the face. These facial tract fibres decussate to opposite sides in the middle of the pons variolii terminating in their nuclei.

*B.* Posterior to this we have the pyramidal motor tract or the will tract of Spitzka, those destined for the arm centers in the cord lying anterior to those destined for the leg. These control the voluntary muscles or movements of the limbs.

*C.* Posterior to this we have the sensory tract which convey sensations of all kinds from the peripheral organs to the cells of the cerebral cortex where they can be appreciated by consciousness.

*D.* Next in order is the speech tract, whose fibres allow of communication between the speech area of the cortex and nuclei of origin of the facial, glossopharyngeal, pneumogastric, spinal accessory and hypoglossal cranial nerves.

This center is also connected by association fibres with the centers of hearing, viz: the first temporal convolution, and those of sight, viz.: the occipital convolutions. Thus the cortical center of coordinated speech movements is capable of receiving excitation from the center of hearing when replies to spoken language are demanded, and from the centers of sight when written or printed language calls for a verbal reply. It is also put in communication, as we have already seen, with the nerves which preside over the apparatus of speech.

*E.* The optic fibres pass through the extreme posterior part of the capsule. These are designed to join the optic nerves with the convolutions of the occipital lobes. This constitutes the visual tract.

*F.* Another tract in the capsule is the hypo-glossal tract. This is an independent tract of fibres which connects the cortical centers for the movements of the tongue with the nucleus of origin to the twelfth cranial nerve within the medulla. It therefore probably joins the lower third of the pre-central or ascending frontal convolution with this nerve. It is supposed to pass through the internal capsule near its knee, and anterior to the motor fibres which govern the limbs. Lesions of this tract would produce symptoms allied to those of Duchennes disease, viz.: Bulbar, or glosso-labio-pharyngeal paralysis.

*G.* The course of the fibres associated with the rest of the special senses, viz.: those of taste and smell, are not yet so well understood as in the case with the eye and ear. This latter, or auditory tract,

probably passes through the lower and posterior part of the internal capsule to its respective centers in the temporo-Sphenoidal lobe.

From the course of the various cerebral tracts, we learn that any lesion which lies in the centrum ovalle at any point posterior to the pre-central suclus of the frontal lobe must necessarily either effect the motor, sensory, visual or auditory tracts, or individual fibres of these, and the symptoms of their derangement will necessarily correspond to the parts affected. Bearing also in mind the following rule of lesions confined to the motor area that the nearer the lesion is to the cortex the more liable will only one center be affected; hence monoplegic paralysis usually results. While the nearer the lesion is to the capsule the more liable two or more tracts are to be affected; hence hemiplegic paralysis together with hemianæsthesia usually occurs.

The importance of this knowledge cannot be over estimated, as by this we are enabled to decide upon the possibility of relief by surgical interference, as well as to define the special nature and seat of the lesion. While it must be confessed that the study is very tedious and complicated, yet the conclusions to be reached are of the highest importance to the patient as well as physician.

As the various facts embodied in this paper are scattered at intervals throughout the wide domain of medical literature and therefore not easy of access to all, I have endeavored to collect and present them in as tangible a form as possible, trusting they may prove of service to any who may be called upon to treat the more obscure diseases of the brain and spinal cord. I might also add that in the preparation of this paper I have made free use of the opinions and statements of such authors as Spitzka, Ferrier, Hughlings Jackson, Horsley, Gowers, Charcot, Nothnagle, Edinger, Ranney, Luys, Flechsig, Gray, Sachs, Starr, and Dana, as well as many others, besides the cullings from the numerous periodicals devoted exclusively to neurological science.

# COMMUNICATIONS.

## BACTERIOLOGY AND COUNTRY HYGIENE.*

K. S. HOWLETT, M.D., Bigbyville, Tenn.

In these, the closing years of the Nineteenth Century, scientific research is being carried on with a zeal and an enthusiasm unknown to any other age. Men are becoming more unselfish and self-sacrificing n their pursuit of knowledge, are giving their time and their fortunes and devoting their very lives to the attainment thereof. In every science, the devotees are carrying their investigations deeper and deeper, and the wonderful scientific mysteries unfolding in response to their endeavors only seem to whet the appetite and increase the unsatiable desire for further knowledge. As a result of this untiring work, wonderful progress is being made in every science and, the best of it all is, this knowledge obtained is being used for the elevation, the advancement and the comfort of the human race.

In this movement, the science of medicine does not lag behind. In no other field is there greater display of earnestness, zeal, pluck and determination and in none other are there more brilliant and at the same time more practically beneficial results. In no other profession, without any exception, has there been manifested more modesty, unselfishness and self-sacrifice, more of that greatest of all virtues, charity, or love of fellowman, and in none other has there been more ardent, disinterested work done or more heroism shown in attempting to relieve suffering humanity and no other more deserves the admiration and the gratitude of the whole world.

Every true physician must feel an added heart beat of pride in his profession when he contemplates these things.

That branch of medical investigation which has been given the most attention, which has already made the greatest

*Presidential Address, delivered before the Maury County, Tenn., Medical Society.

change in our therapeutics and which bids fair to well-nigh revolutionize our ideas about many diseases and their treatment, is the study of bacteriology. A few years ago it was given only a passing thought and spoken of (if spoken of at all) only indifferently or contemptuously; but to-day these little parasites are taking quite a prominent position in the medical world. The most distinguished investigators are fairly living among them, cultivating them, studying their nature, their appearance, their habits, their products and the effect of themselves and their products when introduced into the system; the most progressive medical schools are adding special laboratories for the study of them, medical lectures and essays are replete with them and the medical journals are full of them. Now, the outside world is catching on and the newspapers are giving space to them and even the patent medicine advertiser has a knowledge of their existence and is trying to turn them to a profit by promises of a complete, sure and universal destruction to them.

These innumerable little pests float in the air we breathe, in the water we drink, live in the food we eat, hide themselves in the carpets, on the walls, and in every crack, nook and corner of the houses in which we live, and so great is their tenacity to life that they live on for months and years, resisting heat and cold and almost every effort we make for their destruction, even daring sometimes to take up their abode with impunity in some of our boasted disinfectants and multiply and develop there.

They are continually and persistently seeking an entrance into the body that they may find a congenial soil and set up their destructive process there. Having once forced their unwelcome entrance into the body and found a suitable place upon which to plant their batteries and establish their head-quarters, they put their chemical laboratory to work and manufacture poisoned ammunition with which to carry on effectively their fierce assault upon every vital fortress. They send these destructive products into the brain, the heart, the digestive organs and each shows the disturbing effects of their presence and each trembles, weakens and well-nigh succumbs to the unwonted invasion.

But nature does not tamely submit to this intrusion upon her domain and the bacteria do not find an unmolested march or an unresisting or easily conquered inhabitant. For within the body are found living cells, or phagocytes, which stand ever on guard, keeping up a close and ceaseless vigil, ever ready and waiting to rush to the rescue and repel the advance of any destructive army. Hence, we have an uncompromising warfare between cells and parasites, between native inhabitants and foreign invaders. As the bacteria exert their destructive influence chiefly through the agency of chemical poisons, so likewise the living cells use their counteracting poisons as a means to destroy them and render inert their products. This contest is one that knows no truce. Each side carries the black flag and it is a war of extermination and so fierce do the combatants become that the conquerors even devour the dead bodies of their adversaries.

While this savage interchange of hostilities is going on and this furious battle raging, all is noise, strife and confusion within the system. But when the victory (as, fortunately, it usually does), perches upon the banner of the living cell, and the smoke of battle has cleared away, we find that every evidence of the ferocious contest has been removed and all is peace, quiet, order and regularity. Once more, not only this, but the industrious little cells often go further and so fortify the system that forever thereafter they can easily protect themselves from the future assaults of these same bacteria and give the body an immunity from them.

So nobly, so brilliantly and effectively do these little cells do their part, and so many valuable lessons have they taught the close and wondering observer, that the admiring physician looking on feels like bowing in humble respect before them and deems it an honor to be an ally to such courageous heroes and a coveted privilege to be a disciple of such judicious teachers.

This so-called doctrine of Phagocytosis is an interesting and fascinating one, and while many will call it only a beautiful theory, it has already added something to our therapeutic resources and promises much more for the future.

But while the study of bacteriology has added much to our knowledge of the etiology and pathology of diseases and has aided us materially in

the rational treatment thereof, perhaps the greatest benefit we have derived from it and the greatest advancement that has been made is in that art which is the perfection of all medical skill, viz.: the prevention of disease. Knowing these little germs to be the cause of so many of the ills which flesh is heir to, there is nothing more natural than that the greatest effort should be made to prevent their entrance into the body.

Now, the first thing we notice in studying bacteria, is that dirt and filth are the most congenial soil for their propagation and development; hence that most important of all hygienic laws, always appreciated, but now that we understand the habits of these parasites, more so than ever before, that cleanliness is absolutely essential to health and that filth is the most prolific cause of disease. The cities and larger towns have long since learned, by sad experience, the fatal results of neglecting this, as well as other hygienic laws, and have conformed their laws and customs accordingly. They locate and build their houses with due regard to drainage, ventilation, sewerage, etc., so that they can have pure, fresh air to breathe; they arrange their water-works so that they can have good, clean water to drink; have boards of inspectors to see that they have wholesome food to eat, and most important of all, they give their boards of health power to compel every man to clean up his premises, disinfect privy vaults and cess-pools, and to see that nothing is allowed to be carried on or to remain on one's premises which would be a nuisance or source of danger to the health of his neighbors. The result of this is that we have cleaner cities, with better health reports and a constantly decreasing rate of mortality and an almost complete suppression of the former fatal and dreaded epidemics. Where so many people are crowded together, the necessity for such precautions forces itself upon the attention of people and in pure self-defense they *must* not neglect them.

But, while this improvement has been going on in the cities, what has been done in the smaller towns and country? Nature is exceedingly kind to the country inhabitants. She furnishes them with fresher air and purer water, if not polluted by man himself, than the cities can obtain with all their improved appliances, and the people have become so accustomed to think of the country as the place for city people to go for health, and they have neglected the best known laws of hygiene for so long, with comparatively few bad results, that they never think of such things until sickness and death comes and they begin to look around for a cause thereof. I wish to direct your attention for a very few moments to some of the very noticeable conditions frequently found in reference to country hygiene. First, we will notice the water supply. Sometimes we find several members of a family stricken with a fever, generally typhoid, at the same time, and, in looking for a cause, we will investigate the water supply of such a family. We will generally find an old well, which probably has not been cleaned out for years, located in the lowest part of the premises, so that all the filth about the yard and (perhaps) lot must necessarily drain right into it. Or, you will find a spring down in the stock lot, with horses, cattle, hogs and geese running all around it and the spring branch choked up with grass or leaves. I recall one of this kind. In the family of the owner of the place I had five cases of typhoid fever following each other in quick succession, and in the house of a tenant, who used water out of it, I had three or four cases, while among the pupils of a school, who got their water at the same place, I had several cases of both typhoid and malarial fevers. Of course, my attention was immediately directed to this spring. I found it located about thirty yards from the house, at the foot of a little hill, upon which was situated the residence with all the out-houses (a condition often found), the branch from it choked up with half-decaying weeds and grass, so that the stream could only make its way sluggishly and laboriously away. And, just above this spring, I found a large hog-wallow, separated from the spring by a mound apparently thrown up for the purpose, about twenty feet through, and a muddy, slimmy stream from this flowed right down by the fountain of the spring and emptied itself into the branch just a few feet below. It was not only not surprising that they had typhoid and malarial fevers as results, but a wonder that they did not have the whole catalogue of diseases besides. This is probably an extreme case, but if we will ex-

amine the wells and springs from which the majority of even the well-to-do people get water, we will find that that water must certainly be far from being pure and could be wonderfully improved by just a little ditching, a little more attention and by showing a little better judgment in locating the buildings, stock-lots, etc., with reference to the source of water supply. I wish to put especial stress upon this point, for I believe it is most sadly neglected in the country and a most prolific source of sickness, suffering and even death.

Now, when we come to notice the houses in which the people live, according to my observation, very little fault can be found with the dwellings of the well-to-do which have been built lately. They usually select healthy locations for them, and the rooms are generally large and well ventilated. One error that ought to be condemned is that not uncommon one of having cellars under the houses, which are used for storing potatoes or other vegetables in, or for milk houses, and many of which get very damp, having water standing in them at times, and which it is not possible to properly clean out. Going to the rooms of the upper story, another improvement that might be suggested is that they be given more height, as they are generally used for sleeping rooms. We ought also to always protest against the common practice of the whole family sleeping in one room. When we come to look at the outhouses, we frequently find the stables and privy in uncomfortable proximity to the dwelling house, and one very grievous error is the almost universal neglect of using disinfectants of any kind about the premises. Where people live some distance apart, the necessity for this is not felt, but disinfectants are cheap and many cases of sickness might be prevented by their systematic use.

But when we visit the houses of the great mass of tenants upon the farms in our country, we find everything to condemn. They are frequently located close to a branch or creek, in the lowest, wettest place about the whole farm. Almost all of them are built of logs, generally old rotten logs which have already served out their term of usefulness in other houses. These furnish an inviting lodging place for every species of germ. The floors of these cabins are laid right on, or very close to, the ground; the sleepers, if there are any, have usually decayed from the constant damp, and the floor is sunken and uneven. The celling is so low that one can scarcely stand erect in the room. The doorway is low and narrow, and usually (but not always) we will find a little square hole left in the wall somewhere, which serves to let in light and air in the stead of a window.

But it is not necessary for me to continue the description of these houses, for they are so common all over this country, being found upon the farms of our most prosperous farmers, that every physician is perfectly familiar with them and will agree with me that the picture is not overdrawn. In this so-called house, consisting of one room, with perhaps a covered pen behind it for cooking purposes, must live a whole family, oftentimes doing their cooking, eating and sleeping all in the same room, and if any are sick they must remain in the room where this is carried on. As the great majority of these tenants are negroes, who are certainly not noted for neatness, you will readily see what the condition of affairs is and imagine what the results will be. Such seeds sown will inevitably bring forth a harvest of disease and death. Now by sickness the owner of the farm frequently loses the labor of his hired man or tenant for days and weeks when such service can illy be spared, or by death loses him altogether, and it seems to me that not only for humanity's sake, but as a pure matter of business and as a paying investment, they should set fire to; or tear down, these old death traps and build for their tenants larger, more healthy and more comfortable houses.

There are many other means by which the simplest laws of health are most flagrantly violated throughout the country that might be mentioned with interest, especially in reference to school houses and other public buildings, but they are patent to every observing physician and every one duly appreciates the evil thereof.

The question that presents itself to us is, what can be done to mitigate such evils? The inhabitants of this free country are a liberty-loving people, and every man feels that even if he has a condition of affairs upon his premises which brings sickness to his family or tenants, but does not harm his neighbor, it is nobody's business but his; he quickly resents any in-

terference in the matter, and it is useless to try to make and enforce laws to compel him to change these things. But the greater number of our farmers are intelligent, reasonable people, and they would very willingly keep their premises in better hygienic condition if their attention was only directed to the evil of neglecting to do so. But how little attention has been paid to this, even by the physician himself. We see statistical reports from the cities, showing the death-rate and the number of infectious diseases, and we see the causes of these diseases discussed often and persistently in the medical and daily papers, and we see articles from the health officer, making a demand upon the people to attend to the removal of all conditions favorable to the dissemination of disease. But country people seldom ever think of these things at all in connection with their homes. Now wouldn't it be an interesting thing to country physicians if we could get at like statistics concerning the country neighborhoods? And could'nt we, by a little work, make the report of the county health officers less vague and more valuable? Suppose we appoint a statistician, and let each physician report to him the number of deaths, of infectious diseases, calling especial attention to those that are due to improper hygienic surroundings. Let the statistician tabulate and arrange these reports, publish them with appropriate remarks each month, and call the attention of the people to the preventable causes of disease, and urge them to clean up their premises, look after their springs, disinfect privies, etc., just as city health officers do from time to time. It would certainly be a wonderful improvement upon the present manner in which indefinite reports come to the health officer, from which he makes his report, and would add much to the accuracy, interest and true value of such report, both to the physician and the people.

## DISPUTED POINTS IN HYSTERECTOMY.*

JOSEPH PRICE, A.M., M.D., Philadelhhia, Pa.

The mooted questions in surgery grow less as our experiences enlarge and ripen. There are in our science and art some certainties, some points upon which there is unanimity of enlightened opinion. There are, however, also, as in all other sciences and arts, as in all other lines of human enterprise and endeavor, disputed points; disputed, we must take it, from the standpoint of conscientious opinion. These differences are the chief factors, the motor forces of our advances. Without them, inertia would take the place of our activities. The fact of our advances is not disputed; the lines along which they have been made, direct the way of interesting and instructive study. We have a profound interest in the names and work of those toiling pioneers who have blazed the trees for our guidance to lessen the difficulties of our following. What they have done for womankind will always lie beyond the power of biographical pen to narrate. We would find it difficult to distribute our debt of obligation when we come to consider the great labors, the brilliant work of McDowell, Kimball, and the Atlees, of Péan, Keith, Koeberle, Hegar, Billroth, Kaltenbach, Kleeberg, Schroeder, Lawson Tait, Bantock, Thornton, and others. We find stimulus in such names and such records for worthy following. They have given us the sublime lessons of their experience. What masters they are—all of them! They represent the genius of science, of practical skill; they have enlarged our resources; they have helped us to make many lives worth living. Some of these men are living to-day, are yet giants at the wheels, yet students in the solution of great surgical problems.

In considering the definitions of hysterectomy we must bear in mind nomenclature. Schroeder's term, myomotomy, is not synonymous with hysterectomy; is not hysterectomy; it more appropriately applies to simple extirpation of the tumor. Hysterectomy is the removal (Kimball's operation) of the whole body, or any section of the uterus, with

* Read before the Philadelphia County Medical Society, April 12th, 1893.

tumors inseparable therefrom. Such high authority as Thornton places within its field all cases in which the uterine cavity is laid open and more or less of its wall removed along with the fibroid; whether one or both ovaries are also removed is a matter of no consequence. Sometimes it is more convenient to remove one or both, applying the term vaginal hysterectomy to cases in which fibroids, the uterus, and the uterine appendages are all removed.

The progress made in perfecting the operation has taken some disputed points out of the field. Experience has given something of definiteness to our views; still there are two camps. The disputed points involve methods, rather than questions, of the justifiability or safety of the operation; on these points there is unanimity of sentiment among experienced surgeons. There may be yet some division of opinion as to what cases should be operated on, and what cases should be let alone. The operation was long regarded as one of the most fatal in surgery. The low rate to which the mortality following the operation has been reduced, where the cases fall into experienced and skilful hands, has given it an abiding and important place among the life-saving procedures. In the matter of methods, men are likely to credit those methods with being best which, by their own tests and in their own individual and professional experience, have given the best results. One or more failures with any one particular method of procedure drives some men to try others. With their first success they christen the baby "My method," "My modification," "My improvement," or "My invention," and the entire profession is exceedingly glad that a new genius has been born into the profession—that there is a new light in Israel.

The history of the treatment of the pedicle in ovariotomy has influenced all of the older ovariotomists to try the same methods and materials to perfect an intra-peritoneal method in hysterectomy. The early efforts of Schroeder were quite successful. Some of the younger operators have improved the statistics by clean extirpation, but we yet remain in two camps as to the management of the pedicle.

Operators clinging to the nœud and the extra-peritoneal method are making the best showing, operating right along with a very low mortality. It cannot be inferred from the success of the intra-peritoneal method in ovariotomy that improved or equally successful results will be attainable by the intra-peritoneal method in supra-vaginal hysterectomy. The results in many large and ripe experiences establish the fallacy of this idea; such inference is in blind disregard of essentially different conditions. Ligatures cannot be safely used in uterine, fibroid, or myomatous tissue. Silk, as applied to the pedicle in cystomas, is harmless and safe.

I would say here that the earlier errors in diagnosis, mistaking cystiform degeneration, fibroids, or œdematous myomas, for ovarian cystoma were common, and the cases were either abandoned or incomplete operations done with disastrous results. Some of the most skilful operators did not escape making these errors.

The treatment of the pedicle has been repeatedly and exhaustively discussed. Results have dampened the enthusiasm of the advocates of the intra-peritoneal method.

It is necessary in the removal of about all fibroids to make a pedicle. Its manufacture in extra-peritoneal hysterectomy is the one important feature of the operation. It should be made small. Suturing securely against hemorrhage is also the important feature in the intra-peritoneal, and the avoidance of hemorrhage and the ureters are the important features in the extirpation method.

Shock is minimized in the extra-peritoneal method, the operation being shorter, exposure and manipulation less, than in any of the intra-peritoneal methods.

The method of turning the pedicle into the vagina is a tedious operation; the risks of hemorrhage and of injury to the ureters is even greater than that of a clean extirpation of the cervix.

The question is often asked, "Why leave the cervix or stump in at all; it is the most common source of hemorrhage and sepsis in all the intra-peritoneal methods?" Its removal is the perfected operation, but the results as yet have not been as good as in the extra-peritoneal method of treating the stump.

Hemorrhage is incident to the supra-vaginal, as it is to all the methods. The bleeding varies greatly, and sometimes is absent altogether. In this procedure the elastic ligature (Kleeberg's) and the wire ligature minimize the risks of hemorrhage.

The chief danger in the intra-peritoneal method is bleeding from the pedicle. Drainage, or the dry treatment, where adhesions have been extensive, is of vital importance in these operations. It is an important object to get and keep the stump dry. In some cases you need not change the dressings for a week or more. They should be changed when they become moist. The advantage should be kept in mind of sewing the edges of the peritoneum across the stump, thus preventing retraction when the loop has become somewhat loose from the shrinkage of tissue. The duration of the operation is one of the many factors to be considered. There should be that rapidity consistent with due caution and scrupulous attention to essentials. There is no time for fussiness. There is the shock of the anæsthetic. Extensive adhesions, bowel and bladder complications, require painstaking surgery, and tedious and slow the steps of the procedure, and somewhat lengthy, however deft and educated the hands engaged. Temperature is an important consideration. Supplying dry heat throughout the operation will avoid, to a very great extent, the shock due to the chill of the atmosphere. In the matter of shock, long exposure and long anæsthesia count for much. It should be kept in mind, however, that to deal with an abdominal wound carelessly or too hurriedly is bad surgery. Every step should be timed to the needs of the case, every motion those of a master workman, and there should be summoned into service every resource of our science and art.

When we come to consider hysterectomy in all its phases, the condition of the patients when they come into our hands, the dire extremity that drives them to us, that they come to us with general health broken down, often complete physical wrecks, and familiar as we are with resultant issues—we have no difficulty in appreciating the difficulties we have to encounter. The professional responsibility is a heavy one. The patient's condition suggests the urgent question: "What should be done?"

We appreciate the truth of J. Knowsley Thornton's statements, we accept them in the main as surgical truths, into the acceptance and practice of which the profession should be educated. As to the relative value of two very diffierent surgical procedures for the cure of fibroid enlargements of the uterus, he says: "I feel that I am confronting one of the most difficult questions in abdominal surgery armed with imperfect weapons. Medicine has long and vainly endeavored to deal satisfactorily with this disease, and now the surgeon's aid is invoked. I do not deny that many cases have been relieved by medical treatment, and that some have been cured while under such treatment. I do think, however, that it is an open question how many of the cases cured while under treatment were cured by the treatment, and I believe the majority of such cases have been due to the co-incident interposition of Dame Nature.

"A very large number of patients never suffer pain, or even inconvenience enough to make them consult either physician or surgeon. But admitting all this, there undoubtedly remain a large number of cases urgently demanding surgical aid. Some patients are brought face to face with death from hemorrhage, excessive growth of the morbid elements, or constant interference with rest from pain and discomfort. Others are gradually but surely reduced in strength, and have lesions of vital organs as the result of constant pressure and displacement. When surgical treatment is spoken of, we are told that we have no right to interfere with fibroids as we do with ovarian tumors, because the latter surely kill if left alone and the former do not. I am certain that this argument is only partly true, and everyone who sees a large number of cases will bear me out in the statement that numbers of women die every year from the direct and indirect effects of fibroid enlargements of the uterus.

"I would ask, How much of the general surgery of the day which is dangerous to life would continue if surgeons ceased to perform operations of expedience, that is, to operate for deformities and diseases which do not endanger life in themselves, though they deprive their victims of all the pleasures of life? I affirm, then, that there are many cases of fibroid enlargement of the uterus which endanger the lives of their bearers, and that there are many more which make these poor suffering women so miserable and useless that they are justified in running the risks of operation, and that the surgeon is justified in operating. We must remember that these operations are usually undertaken

in extreme cases, and when the patients are worn out with disease and suffering.

"The operation of complete supra-vaginal hysterectomy, with removal of both ovaries, has become, when properly performed, one of the most successful of the great operations.

"Hegar and Kaltenbach, by their new extra-peritoneal method, have saved eleven cases out of twelve, and the surgeons at the Samaritan Hospital have in the last year had equally successful results, also by the extra-peritoneal method, using Kœberle's wire serre-nœud in much the same way that Hegar uses the elastic ligature. These operations of hysterectomy and complete supra-vaginal hysterectomy still remain, however, very formidable operations. They are terrible mutilations; the patients are slow in convalescence. Is there then no operation of less danger, of quicker convalescence, and of better and more perfect results which we, as surgeons, can recommend to our patients.

"Thanks to American surgery, the brilliant conception of Blundell, in 1823, was made a recognized surgical procedure by Battey, in 1874, and from the labors of Hegar, Trenholm, Tait, Savage, and others, I am able to present to you a perfected operation, which will render this formidable hysterectomy still less often necessary in the future than it has been in the past.

"The complete removal of the uterine appendages, when efficiently performed, cures fibroids of the uterus with rapidity and certainty. And I will ask you to remember that this operation is not such a serious mutilation, and does not leave behind it any mark except a small linear scar on the perfectly closed abdominal parietes. The removal of the uterine appendages is attended with infinitely less danger to life than are the various operations for the removal of uterine fibroids.

"Are we then justified in subjecting our patients to the formidable operation of supra-vaginal hysterectomy when we can cure them by removal of the uterine appendages?"

It should be accepted as a settled fact that we are never justified in doing a hysterectomy when the appendages can be removed early in the growth of the tumor.

---

## DIABETES INSIPIDUS

F. P. BUTLER, M. D., Marshalltown, Iowa.

July 3rd, '92, was called to see Mr. P. V. J., æt. 73; was informed by the messenger that he had diabetes, and was requested to be prepared to make an examination of the urine at the bedside. 20 years ago, he noticed that he had to get up once, and some nights 2 or 3 times to urinate; has always been a strong man living on a farm all his life; had never used liquor of any kind; in December, '91, his wife died, the blow was a very severe one to him, he not allowing the family to mention her name in his presence. In February, while asking the blessing he would suddenly stop, get up from the table, rush bareheaded out of doors, remain for some time, return and probably pick up a paper and read awhile, then go about his work; this proceedure was liable to be repeated at any meal. At this time there was a noted increase in the flow of urine; he consulted a physician who told him it did not amount to much and would soon pass away. He took a trip East and returned in a few weeks much improved; this was in April. His son who was in the West, desired him to meet him in Salt Lake City in May. He made all arrangements to do so, when he received a letter from his son, telling him that he could not be at Salt Lake by May first but would be soon. The son, being detained, kept writing that he would go soon, when, 10 days before I saw him, he wrote telling his father he would have to put off his trip for a long time. This affected the old man greatly, and at once there was a noted increase in the flow of urine; his head pained him very much and it was almost impossible for him to sleep, in fact it brought on an acute attack of his (I think) chronic trouble. He received one injury to the head in youth, it was slight and lasted him for a short time only; he has never had but one sick spell, that was typhoid fever years

ago, from which he recovered completely; his habits have always been active and steady; he has taken excellent care of himself.

At my visit, I found him very much exhausted, with neuralgic pains through the head and extending to the back and hips; he had for nine days been passing an ordinary chamber full (110 oz.) of urine in twelve hours. I applied Fehling's test but the result was negative. I prescribed F. E. Ergot m. 12, once in four hours, to be alternated with 8 grains of phenactine. Securing a sample of urine I repaired to my office and made a more thorough test, and found no sugar and a sp. gr. of 1000. His mouth was dry and he, of course, was very thirsty, drinking about as much water and other fluids as were eliminated by the kidneys; bowels constipated; relieved by pil. cascara sagrada gr. 2.

July 4th, a sample of urine was brought me in the morning; the color was better; the sample of the day previous being the color of water, no sugar, sp. gr. 1002, the amount passed being one third less than that of the twelve hours previous; he had a very comfortable day, appetite fairly good, for the past two weeks it has been very poor; the evening sample of urine being being the same as that of the morning.

July 5th, rested about the same; passing the same amount of urine as on the third, increased the ergot to thirty drops, continued the phenacetine, appetite not improved, still very thirsty, slept better than he has for several nights; in the evening increased the ergot to one teaspoonful t. i. d.

July 6, Dr. L. saw him in consultation; confirmed my diagnosis; patient much the same as yesterday, possibly a little more exhausted; his appetite being so poor we gave extract beef, also brom. potass., grs. 10 in place of the phenacetine, urine same as yesterday. July 7, rested well last night; urine darker color; sp. gr. 1002, slight decrease in the amount; took more nourishment than usual, strength about the same; continued treatment. P. M., amount urine passed in eleven hours 124 oz., sp. gr. 1001; increased bromides to 15 gr. July 8, A. M. Some stronger to-day, ate a hearty breakfast, slept well during the night, mouth was less dry; from 6.45 P. M. to 7 A. M. he passed 114 oz. of urine, 10 oz. less than during the preceeding 10 hours; continued treatment with orders to nourish him as much as possible; headache better; from 7 A. M to 7 P. M., July 8, passed 135 oz. of urine, but seemed no worse for it, sp. gr. 1001. July 9, from 7 P. M., July 8, to 7 A. M. July 9, amount of urine passed 90 oz., less than he has passed since he was taken sick, sp. gr. 1005, the highest I have found it; slept very well all night, ate a hearty breakfast, bowls moved by enema, mouth less dry.

He gradually grew worse from this time up to the 23d; several times we thought he could last but a few hours longer; the morning of the 23d, his long-looked-for son arrived and he at once commenced to improve, and by the 3d of August he needed no medical care, and in a week or two left for the west, where he regained his original health.

This I think a case of diabetes insipidus, brought on by mental trouble in the loss of his wife, and by the great disappointment in not meeting his son as he had expected, and very much desired to do; it is purely nervous, because there is not a trace of his trouble that will show that it was brought on by anything else.

---

## REPORT OF INTERESTING CASES IN ABDOMINAL SURGERY.

M. PRICE, M.D.

Dr. Henry Leaman has kindly consented to allow me to report this case of mechanical obstruction of the bowel, as it is one of great importance, and it is his report I give and not mine. You will remember a similar case reported for the same trouble nearly two years ago, and as that case was one that many thought strongly reported I thought best to call your attention to this one reported by Dr. R. Leaman and operated by Dr. Henry Leaman, and I had the pleasure of assisting in the work.

Dr. Leaman's Report.—I was called to see Thomas P. on November 1, 1892, who presented the following conditions,

viz.: retention of urine relieved by the catheter, no passage from the bowels for three weeks previous, when he had done heavy lifting and active work. My idea was that there must be invagination or twisting of the bowel, and treated him after the usual methods both by mouth and rectum, still nothing in way of relief was accomplished; the enlarged adbomen grew until the tympanitic condition gave place to a slightiy dull note everywhere over the abdomen on percussion from excessive distention.

The vomiting, which was always present, now became somewhat stercoraceous. Respiration became shallow, rapid, and feeble from the encroachment of the diaphragm. Pulse feeble, mind wandering. But with all this the temperature never rose above 100°. On November 10, 1892, I called in my brother, Dr. Henry Leaman, in consultation. It was at once decided that nothing but an operation would give the patient any chance. Dr. M. Price was asked to see the patient and assist in the operation. All abdominal pain had ceased about three days.

The operation was done in a little room in Carleton Street, and, as usual to the location, the environments were not of the best. The patient was taken from the bed and placed on a table and a median incision made as in abdominal operations; the bowel enormously distended with liquid. A search was made for the point of obstruction, but I could not find any. Dr. Price also made an effort to find the obstruction. Failing to find one, we decided to open the bowel and empty out its contents and then make a thorough search for the obstruction. This also failed. The bowel was carefully stitched and the patient put to bed. In the next forty-eight hours he had about thirty evacuations. The bladder had to be relieved with a catheter. He made an uninterrupted recovery.

Mr. K., patient of Dr. Romaine, of Lambertville, N. J., aged thirty-two years, had had a number of recurring attacks of severe pain in the region of the appendix, all of which, save the last, have yielded in two or three days to purgation by salines. Last attack occurred May 2, 1893, and he was at once freely purged. This gave considerable relief; but the pain would return in twelve or fourteen hours in as much severity as ever. It was decided to have an operation, and I was asked to operate.

May 7. I carefully examined the patient, and from the history and the existence of peritonitis, and the fact that all his pain and suffering came from the region of the appendix, also that he had had a number of attacks with the same symptoms, I did a section and found from three to four feet of ileum adherent in mass over the head of the colon, greatly adherent and covered with inflammatory lymph. There was some pus in the mass, but very little. The bowels were completely separated, washed and replaced, and then the appendix looked for and found in a hard mass curled up and adherent to the head of the colon on one side and to the pelvic bone on the other. The adhesion to the pelvis was loosened, the appendix and bowel were brought out, but the bowel could not be removed without great injury. So, with thorough irrigation of the peritoneal cavity, stitching of the lower end of the wound, the hardened mass at the head of the colon, with the appendix attached, was placed directly under the upper edge of the wound and over it a gauze drain, which was left in place for thirty-six hours; afterward dressed daily.

Patient had no increase of temperature or pulse after operation, and made an uninterrupted recovery.

Mrs. H., aged forty years, suffering from great nervous prostration, constant pelvic pain for the last two years. She was treated by Dr. Peltz, her family phsician, with great patience and care, but without any lasting benefit.

I examined her in February in consultation with Dr. Peltz, and found no marked pelvic disease—nothing that warranted an operation. In one week after my visit she was examined by a Philadelphia gynecologist who used an instrument to measure the depth of the womb, and its freedom from adhesions. The instrument gave her violent pain and greatly increased her suffering. May 4th. I again examined her and found the uterus fixed, and on the left side a large fluctuating mass —right side adherent. May 6, 1893. I did a section and removed a large ovary tand tube distended with blood-clot, contents measuring about half a pint of decomposing blood and pus; the right side a pus tube.

How much this trouble was due to a

previous existing disease, or how much to the intra-uterine examination, I leave you to judge.

Herbert H., son of Dr. H., of Pemberton, N. J. Appendicitis. Operation; drainage; recovery. This is the third case in eight months that I have seen in the hands of this physician—two operated on and recovered. The third, a young man nineteen years old. When I was called he insisted he was much better, and would not submit to operation. He had well-marked symptoms of abscess of the appendix. He continued to improve, and for three months afterward declared to Dr. H. that he was perfectly well. While unloading a can of milk he felt something give way in the right inguinal region and died in twelve hours, before anything could be done for him, of peritonitis.

## GANGRENE OF FOOT AND LEG.

B. H. POTTS, M.D., PHILADELPHIA, PA.

I wish to call attention to a few cases of gangrene of the foot and leg that occurred during the service of Dr. Willard in the Pennsylvania Hospital, and mention one case particularly that shows the efficiency of the high operation performed as early as possible.

### CASE I. GANGRENE OF FOOT—RECOVERY.

Man, æt. 42 years. Had always been a healthy man. Two weeks before admission to the hospital he noticed a pain in the outer side of the left foot and that the little toe of the same foot was black. No history of traumatism of any kind could be obtained. The pain gradually grew worse, and one week after admission the nail of the little toe was extracted. Sharp and lucinating pains now began to shoot from the toes to the ankle. Two days later the gangrenous portion of the toe was removed, and a laudanum poultice applied. At the end of another week the entire toe was removed. About this time the glands of the left groin became enlarged; ung. hydrarg. was applied and under this treatment they gradually improved. The wound of the toe healed at the end of ten days, and one week later patient was discharged cured.

### CASE II. GANGRENE OF FOOT WITH ERYSIPELAS—DEATH.

Patient was admitted to the hospital in 1883. Twenty years before this his left leg broke out with ulcers on the inner side of the tibia, which discharged until six months before admission, when they healed leaving cicatrices; about this time his right foot began to trouble him. At this time also, six months before admission, his right foot was frost-bitten, and steadily grew worse. The outer side of the great toe became sore and painful, and this condition extended to the inner side of the foot. On admission the great toe was gangrenous throughout its extent; there was considerable sloughing at the end, and its nail had come off; the second toe had also lost its nail and both were cold and insensible. Vessels were tense and thickened, but not atheromatous; glands in the right groin were much enlarged. The slough gradually extended along the inner side of the foot, leaving the metatarsal bone of the great toe bare and necrosed. The muscles on the sole of the foot had sloughed to within two inches of the inner malleolus. This slough was gray ashen in color, had a very offensive odor and was painless.

The foot was dressed daily with boroglyceride for one week when a charcoal poultice was applied. One by one the toes were removed, until at the end of five weeks all the toes of the right foot were gone. The granulations now became purple and livid; there was no soreness or pain. Inflammation of an erysipelatous character set in, and the general condition became very poor. Patient was given tr. ferri. chlor. and quinia. The gangrenous process slowly advanced until the slough extended to the ankle. The patient began to steadily lose flesh and strength and died from exhaustion at the end of seven weeks.

CASE III. GANGRENE OF BOTH LEGS—DEATH.

Man, æt. forty-four years. While exposed one cold day patient's feet were frozen, the left one more severely than the right. During the six months following the exposure, but little attention seems to have been paid to the feet, but the process of gangrene started and steadily advanced and at the end of that time, the line of separation having formed, the toes of the left foot were amputated. On the day following the operation, gangrene of the stumps ensued and when patient was brought to the hospital, one week after the operation, the gangrenous process had extended to the knee on the anterior part of the leg and a few inches below the knee posteriorly. Inflammation extended half way up the thigh which was greatly swollen and crepitant. Patient was very weak; arteries were atheromatous.

It was decided to wait until patient's condition improved and he was put on a course of tonics and stimulants. The leg was dressed with a hot solution of bichloride 1-1000 and wrapped in cotton and wax paper. The line of demarcation formed at the end of ten days. Patient's condition was improving slowly but steadily. Two weeks after admission, a small black spot appeared on the great toe of the right foot which was very painful, but did not spread. Four weeks after admission, the gangrenous portion of the left leg was taken off at the knee joint; the tissues were all dead and there was no hemorrhage; no sutures were introduced but the flaps were strapped. The end of the femur was black and showed no line of demarcation.

Three days later the patella was dissected away from the soft tissues and the periosteum from the bone and the latter sawed off about one inch and a-half above the condyles. The great toe of the right foot was amputated, but at once began to slough.

At the end of two months the leg stump had entirely healed, but the stump of the toe was discharging profusely. Until this time the patient had seemed to improve, but now the gangrenous process began to extend from the toe to the ankle, involving the whole foot, the inflammation extending to the knee. Appetite became poor and strength began to fail and patient went down steadily until the end of the third month when he died from exhaustion.

CASE IV. GANGRENE OF FOOT.—HIGH OPERATION.—RECOVERY.

Man, æt. fifty-three years. Sixteen years ago a piece of ice fell on the right foot crushing the fourth toe; this wound was carefully treated but was very slow in healing and caused him much pain subsequently. Eight months previous to admission, in the spring of 1892, a horse trod on the right foot and two months later another horse trod on the same foot. After this last injury the fourth toe of the right foot bursted and the whole foot looked unhealthy, especially the toes, looking blue and feeling cold; blisters formed in different places at different times. In the latter part of July, 1892, the fourth toe was amputated; the stump healed very slowly. During August all the toes began to show decided signs of gangrene and the pain increased in severity.

On admission, January 7th, 1893, the remaining four toes were found to be gangrenous and the entire lower half of the foot was swollen, tender and caused severe pain. The urine was free from sugar and albumen. Vessels were atheromatous. An immediate high operation was advised.

January 20th, 1893, the leg was amputated at the knee joint. No Esmarch bandage or tourniquet was used, but digital compression was made upon the femoral artery in Scarpa's triangle, and the vessels caught up as they were cut. The popliteal artery was tied, very loosely, with a broad ligature composed of four strands of No. D catgut. No antiseptic solution of any kind was used in the wound, but a very dry stump was obtained and closed up with catgut drainage.

Patient rallied well following the operation. At the end of three weeks the stump was dressed for the first time and found to be clean, sweet and perfectly united.

Patient was now gotten upon a chair, then on crutches and at the end of seven weeks was discharged. He has reported several times by letter during the past few months and is doing very nicely. Is in better general health than he has been for years.

It is to the last case I would particularly call attention as I think it shows the advantages of a high operation. The case

did not present any favorable symptoms; the patient was weak and emaciated; had been suffering very severe pain for months and was very nervous and excitable. His arteries were very brittle. The gangrenous process was slowly extending up the foot, nearly the whole of which showed signs of inflammation. The result obtained from the operation, however, could not have been better for there was left a firm, solid stump which he will be able to use with perfect safety.

# SOCIETY REPORTS.

## SURGICAL SOCIETY OF LOUISVILLE.

*Stated Meeting, April 10th, 1893.*

Dr. John C. Cecil, President, pro tem. in the Chair.

### INJURY TO HAND—PROPOSED OPERATION.

Dr. Turner Anderson: This young man five months ago received a cut in the hand from a wood chisel; he suffered very little at the time and the wound healed. About a month after he began to suffer considerable pain and the thumb began to swell. He went on working as usual notwithstanding the inflammation and pain.

I think the treatment is plain; there is every appearance of pus and I believe it will only be necessary to make an incision and clean it out thoroughly. This is what I propose to do.

### DISCUSSION.

Dr. A. M. Vance: Dr. Anderson's suggestion as to treatment in this case I believe is the only rational procedure, and there is no doubt in my mind but the trouble will be completely relieved by such an operation.

### TUBERCULAR ARTHRITIS.

Dr. W. L. Rodman: I saw this young man with Dr. Chenoweth, and I am sorry the doctor is not here to give the history in detail. I first saw the patient at the University Clinic and asked him to come out to my office that I might get the whole history. I have a memorandum on a card which I will read, it being a few points in regard to the history that I was able to elicit from the patient himself: R. C., aged sixteen years; parents living and in good health. Gives no special history of tuberculosis; several brothers and sisters living and in robust health. Two brothers died during infancy. Felt perfectly well until December 1st, 1892; at that time commenced to have daily chills about two o'clock P. M., followed by fever and sweats. December 20th, right arm commenced to pain him at the elbow. December 26th, noticed swelling for first time; swelling greater at elbow joint, but not marked at any point. At that time he thinks the swelling was about half as extensive as it now is. While it was painful he could use his arm some. Has had a cough since December 1st last. Lost about fifteen pounds in flesh. Arm has not increased in size for six weeks. I would like to have the opinion of the society as to diagnosis and treatment.

### DISCUSSION.

Dr. Turner Anderson: Is there evidence of disease of the lung?

Dr. W. L. Rodman: Yes, in the lower part of the right lung.

Dr. W. C. Dugan: I operated upon a patient having a condition very much like this at the City Hospital during my term of service there last year. Patient had been treated a number of months for rheumatism and was referred to me from the medical ward. I resected the arm and found it was a condition of refying osteitis; removed the olecranon process,

found the bone perfectly soft; and with a pair of forceps I clipped off the condyles, being careful not to interfere with epicondyles to which the lateral ligaments are attached. There was a good deal of œdema of the arm, which soon disappeared. This patient has a good limb with almost perfect flexion and extension and has regained his health.

In regard to treatment in case referred to by Dr. Rodman: I would excise the elbow, and treat it openly with iodoform dressing.

Dr. A. M. Cartledge: I think it is a case of tubercular arthritis, although the shape is a little unusual. The amount of induration on one side seems unusually low, and looks a little curious. I take it that there is very likely synovitis as well as osteitis. I agree with Dr. Dugan that resection is the proper procedure.

Dr. H. H. Grant: From the examination I made of the case I think it is tubercular arthritis; there can scarcely be a doubt about it, but that one doubt would be that there might possibly be some sarcomatous disease of the joint. There is very little effusion.

Dr. A. M. Vance: What part would the phthisis play in treatment of the joint?

Dr. W. C. Dugan: I should not consider it at all.

Dr. W. O. Roberts: I agree perfectly with the statements already made, that it is clearly a case of tuberculous disease of the joint and resection is the thing to do.

Dr. W. L. Rodman: Everybody has expressed exactly the same opinion that I had already formed in regard to this case. I felt almost positive it was a case of tuberculous disease of the joint, after taking the patient to my office and getting the history. I believe the joint ought to be cut into and very likely resected.

### PARTIAL THYROIDECTOMY.

Dr. A. M. Vance: Here is a specimen I removed from a young man twenty-five years old yesterday. The tumor was just over and a little to the left of the larynx. When an incision was made, the cartilages were completely exposed. At the time I first saw the case I thought the enlargement was part of the thyroid gland. I saw a similar case in this city some time ago, the growth was removed which looked and felt very much like thyroid gland. The history was substantially the same as that of the case reported to-night. In the operation yesterday I found a great blood supply to the tumor, three very large vessels; owing to this I was more convinced than ever that I had removed a portion of the thyroid gland. Dr. Rodman saw the specimen shortly after the operation, and thought the trouble was probably lymphatic. Microscopical examination, however, proved it to be thyroid gland. I will quote the microscopists report:

"Louisville, Ky., April 9, 1893.

Dear Doctor:

The growth left me has all the appearance macroscopically of thyroid gland tissue, and thus it proves itself to be upon microscopical examination; consisting of a frame work of fibrous tissue enclosing glandular spaces, lined with small, flat epithelial cells. The glandular spaces are in part filled with a homeogenous material (colloid), others are filled with round cells (lymph cells).

Diagnosis—Thyroid Gland.

Yours sincerely,

Louis Frank.

Dr. A. Morgan Vance."

This is the second case of the kind I have seen in the last twelve months.

### DISCUSSION.

Dr. E. R. Palmer: Was there much hemmorhage during the operation?

Dr. A. M. Vance: There would have been had I not used clamps.

Dr. W. L. Rodman: I saw Dr. Vance shortly after he removed this growth and he asked me to look at it and give my opinion upon it. I looked at the specimen rather carefully; it was not opened at the time, and told him after my examination that I thought it was a lymphatic gland. I am more certain of that position now since it has been thoroughly opened, notwithstanding the microcopist's report. It has every appearance in the world, color and everything else, of a lymphatic gland, and I am reasonably sure that is what it is. It does not look like thyroid tissue. I have dissected a hundred thyroid glands, and am sure they did not have this appearance. The history of the case furthermore points clearly to lymphatic enlargement rather than to disease of the thyroid gland. We do have growths of

the thyroid that occur sometimes from an accessory portion, but as I have said before this does not look anything like thyroid tissue. Thyroid tissue is purplish red, about the color of liver.

Dr. A. M. Cartledge: I would suggest that Dr. Vance have Dr. Frank make some additional sections in this case. If it is thyroid tissue it has every appearance of having undergone malignant degeneration. I agree that it does not look like thyroid tissue. I know of no change that the thyroid body is subject to which would give it such an appearance, unless it be sarcoma. I have never seen so much connective tissue in any form of goitre as there is in this case, and I am not aware of any pathological condition that would give it this appearance. However, the microscope ought to show just what it is.

Dr. A. M. Vance: Goitre affects the central lobe of the thyroid, the shape being caused by pressure of the skin over the hypertrophy. In the case reported by me the thyroid gland on every side looked like this tissue when it was exposed. This is evidently the isthmus hypertrophied.

Dr. W. L. Rodman: Benign growths from the thyroid gland are practically unknown. The only benign growths or enlargements that we have of the thyroid are originally cases of hypertrophy or bronchocele, and then cystic degeneration of the gland. Malignant disease does sometimes occur, but it is exceedingly infrequent, so infrequent that I doubt if any gentleman here has ever seen one. I have never seen one, and in the absence of benign growths from the thyroid, the comparative rarity of malignant growths of the thyroid, with the history of this case I feel quite safe in saying that it is an enlarged lymphatic gland.

Dr. A. M. Vance: I have very little to add in closing. Certainly I would rather take the testimony of Dr. Frank (who is recognized as one of the best and most accurate microscopists in the city) after a careful microscopical examination, than the opinion of Dr. Rodman or, in fact anybody else, based upon a macroscopical examination of the specimen. If Dr. Rodman will specify some anatomist that he would like to make further investigation of the specimen, I shall be very glad to send a portion of the growth to him. Or if he prefers, I would be glad to divide the specimen with him, that he may have it examined by anybody he desires.

### INTESTINAL RESECTION.

Dr. H. H. Grant: I have a specimen here which is the result of an intestinal resection made upon a living animal two weeks ago. After killing the animal I removed about eight inches of the gut embracing the portion resected, which has not yet been opened, as I wished to exhibit it here with a view of showing how much the lumen of the bowel is diminished, if any; and also to see the result of the resection generally. The animal was thoroughly anæsthetized, the incision made and several inches of the intestine exposed; resection was quickly done by the aid of the clamp devised by myself which I present here for your inspection, and which was also shown at the meeting of the Southern Surgical and Gynecological Society several months ago. The animal was under chloroform thirty-five minutes, eleven minutes were occupied in suturing the intestine; the ends were invaginated in the usual way, continued suturing being employed. By an examination of the specimen you will see there is very little contraction; the sutures have been completely buried; there was no peritonitis; the animal did remarkably well after the operation, and the result is perfect. The operation was done very leisurely, and I am satisfied it could be easily completed in twenty minutes. No plate of any kind was used. I have made this experiment several times, using only one line of suture and the result has been perfect, except in one instance.

This clamp is used only for resection; the ends of the intestine are laid parallel with each other, and the suturing done while the clamp is in situ. It shortens the operative steps very much, renders approximation of the openings absolutely accurate, and defines the limit of the fenestra beyond chance of error. Such a clamp takes the place of skill to a considerable extent.

### DISCUSSION.

Dr. W. C. Dugan: The clamp certainly shortens and simplifies the operation very much indeed. The clamp designed by Dr. Grant is the best contrivance for the purpose that I have ever seen.

VULVO-VAGINAL TUMOR.

Dr. W. O. Roberts: This specimen is simply a vulvo-vaginal gland dissected out to-day. The patient was a young widow who noticed this growth three years ago, and claims that a short time before the appearance of the growth she was considerably bruised during coitus with her husband, that there was a good deal of swelling about the parts and some time after that while bathing she noticed this lump. She has been worrying a great deal about the matter, simply from the fact of the growth being there, and came to the city to have it removed. I have seen a good many such cases and have usually laid them open, not finding it necessary to dissect them out. However, in this case the patient was very anxious to have it removed, which was done very easily and quickly.

DISCUSSION.

Dr. W. L. Rodman: Was the growth on the left or the right side?

Dr. W. O. Roberts: On the left side.

Dr. E. R. Palmer: I see quite a number of these cases, and the question asked by Dr. Rodman brings up a point that I had not thought of before; in three of the cases recently seen by me the enlargement was on the right side. I have never removed but one of them in toto. When this complete operation is done there remains a depressed, hard cicatrix at the point of removal, which is entirely avoided when these glands are simply opened, curetted and packed and provided the operation is thoroughly done, the cure is equally assured.

With reference to the etiology, I believe almost invariably that the condition is of gonorrhœal origin. It is hard to say that this is absolutely the case, but I believe in the vast majority of cases it can be traced to gonorrhœa. The usefulness of the gland is permanently destroyed by these enlargements so far as future function is concerned, whether they be dissected out or curetted and packed; the secretion is unilateral afterward, that is, is confined to the side not diseased.

Dr. W. L. Rodman: I have seen I think five or six cases of enlarged glands of this character in my experience, and my observation has been different from that of Dr. Palmer; I have never seen but one on the right side. I would like to ask Drs. Anderson and Cecil what their observation has been in cases occurring after labor as regards the side affected, and their explanation as to why the left side is more frequently diseased than the right. It has not only been my experience that the left side is far more often affected than the right, but in looking the matter up several months ago, I found that the vast majority of these enlarged glands occurred on the left side. The only case I ever saw occurring on the right side was the last case I saw which was two or three months ago, a patient of Dr. McDermott's. The enlargement was noticed soon after child-birth, patient forty-five years of age.

My experience differs again with that of Dr. Palmer. I do not think I have seen any cases where they could be traced to gonorrhœa. Most of the cases I have seen have been after child birth, in a class of patients above suspicion.

Dr. Turner Anderson: With reference to the location of these enlargements, I do not think I have seen them more frequently on the left than on the right side. Concerning the etiology—it is my opinion that the majority of them occur from gonorrhœal infection. At least I have seen more cases among prostitutes than any other class of women. There is another point of some importance in connection with the etiology. Occasionally after perineorraphy, obstruction of the external duct is sufficient to cause cystic degeneration of the gland,—which we must recollect is of the same character as the mammary and other glands of the body, and just as liable to undergo cystic degeneration. I have a case now that came to me a few days ago with a tumor in the left side of the vagina which I diagnosticated without any difficulty as an enlarged vulvo-vaginal gland, which has probably undergone some kind of degeneration, as it has attained a considerable size. This patient was operated upon in Cincinnati for lacerated perineum, and it is probable there is obstruction of the external duct, which we know opens just within the ostium vagina. I do not expect to find an abscess, but believe the function of the gland has been interfered with by occlusion from the operation of perineorraphy. The case was a satisfactory one as regards the operation, but it has probably obstructed the gland. This is a matter that

ought to be taken into consideration in perineorraphy, but at the same time I do not see how it can well be avoided.

With reference to the point raised by Dr. Palmer concerning the treatment of these cases—incision and packing, and in that way preserving the symmetry of the parts, preventing shrinkage or depression—I do not know that my attention has been especially directed to that. The usual operation is to simply incise the gland, pack and let it heal from the bottom. But in the case just referred to, upon which I shall operate in a few days, I believe I will adopt the plan followed by Dr. Roberts, and dissect out the gland bodily. I think this is advisable owing to the size of the gland.

Dr. J. G. Cecil: The point made by Dr. Palmer seems to me to be the correct one in regard to the etiology, as far as my reading and observation go, that these enlarged glands are largely due to gonorrhoeal infection. The point made by Dr. Anderson concerning the class of patients, I think will be borne out by observing the patients in which these troubles are usually found. Certainly, I have seen more in prostitutes than any other class of women. I do not see how they can follow as a result of labor, unless it be in the manner already described by Dr. Anderson as following the operation of perineorrhaphy; that is after the duct was torn across in a lacerated perineum, then we might have occlusion of the duct and cystic degeneration result. I can conceive how that might follow as a result of labor, but I cannot see how there could be any other method of degeneration or abscess as a result of labor.

I was quite impressed with the description, or method of operating described by Pozzi. It is sometimes very difficult in dissecting this gland out, especially when it is simple cyst, to prevent rupture; as long as we can prevent rupture dissection is easy enough, but if rupture occurs then it becomes more difficult, then complete dissection is advocated, it being difficult to follow the cyst wall after it is empty. His method is described about as follows: He introduces a trocar and canula withdrawing the fluid before he attempts to operate, fills it with a warm solution of paraffine, then the application of cold converts the paraffine into a solid tumor, which makes a very nice ground to work upon.

I am inclined to the belief that the total obliteration of these glands is the proper treatment. Of course the function is destroyed if an incision is made and the gland packed; if there is an abscess or cystic degeneration they are of no further use and might as well be removed.

I have never noticed any particular difference in the two sides, and think they are as apt to enlarge on one side as the other.

Dr. W. O. Roberts: I have seen a number of these cases occurring in other than prostitutes. I can recall now three cases in newly married women. This, I take it, is cystic degeneration; I do not think there is any pus in it; it has existed too long, something over three years.

Note: The tumor was opened by Dr. Roberts and found to be cystic.

Joseph M. Mathews, M.D., then read a paper on

### DISEASE IN THE SIGMOID FLEXURE, WITH REPORT OF CASES.

About one year ago, I had the honor of reporting to this society some investigations that I had been making of diseases in the sigmoid flexure. The paper elicited considerable discussion, and I was asked to prolong the report at the following meeting of the society. Inasmuch as the subject was treated at length in my work on diseases of the anus, rectum and sigmoid flexure, which appeared shortly thereafter, the second report was never made. From the friendly reviews of this chapter in the book and from many letters of commendation that I have received from the profession, I take it that the discussion of the subject was not inopportune. This paper is intended only to give a recitation of some cases that have fallen under my observation lately and to mention some procedures looking to the surgical treatment of the same. Although recognized from all time that the sigmoid was a favorite seat of disease, but little was done for its treatment, either in a medical or surgical way, until recently. As far as my knowledge goes, Dr. W. T. Bull was the first to successfully remove the sigmoid flexure for malignant disease. A few months ago Dr. Lange reported three cases of a similar kind, with one success. It must be understood that success means, at least in Dr. Lange's cases, the survival of

the patient from the operation. The time is too short to say whether the eradication of the disease is effectual. Dr. Bull claims that his patient lived five years after the operation. In a note to me concerning the case he says, "The carcinoma was excised in January, 1887; she was in good health up to October, 1891, and there was no recurrence at the autopsy in December, 1891, being nearly five years." Senn has never been a believer in colotomy for any condition, but he has devised other operations to meet the demand. He has anastomosed the ileum into the rectum, and also the colon to the rectum, successfully, and claims, as a result, that if stricture of the sigmoid is to be overcome, his operation would be preferable to an artificial anus, if the opening where the anastomosis was made did not with time contract too much. To carry out the idea of Murphy, that, by using his button, anastomoses of the intestine could be made either end to end or lateral in a few minutes, Dr. Joseph B. Bacon, of Chicago, has just recently been making some very interesting experiments, looking to the surgical treatment of non-malignant stricture of the sigmoid flexure or rectum. Because of the importance and newness of the subject, I will be permitted to quote freely from a late article by Dr. Bacon, describing the method. "The operation consists in completely severing a portion of a loop of small intestine that is lying in proximity to the rectum and anastomosing each end with the rectum, so as to form a new channel around the stricture. The mesentery of the severed piece of gut is left intact. A piece of intestine is selected from the loop, at a point where the mesenteric blood vessels supply a large nutrient artery for each end of the piece to be transplanted. It is necessary to remember, in cutting out a piece for transplanting, that it must be long enough to extend from a point below the stricture to a point above the stricture where the rectal wall is not too much thinned by ulceration; and also to remember that the button to be inserted into each end will shorten the piece about one and a half inches. The operation is completed by scarifying the approximated surfaces of the rectum and transplanted piece of gut and suturing them together, so as to have the two walls united into one firm septum. At a subsequent operation this septum is removed by compression forceps and the lumen of the rectum and transplanted piece is made into one cavity, and the sloughing out of the compression forceps will destroy one-half of the stricture, together with the septum, thus putting an end to the contraction of the cicatricial tissue forming the stricture. The mesentery of the transplanted piece of gut is sutured in close approximation to the parietal wall, to prevent a possibility of a loop of intestine sliding under it and becoming strangulated. A Murphy button is now used to make an end to end anastomosis of the gut, from which the transplanted piece was resected and its mesentery sutured carefully, so as to leave no opening for hernia to occur."

I will make this report by Dr. Bacon suffice for any further mention or discussion of the surgical treatment in such cases, reserving the right to discuss this method in some future article.

There are several conditions which, if left alone, will produce such pathological changes in the sigmoid flexure as to call for the surgical interference as suggested by Bull, Senn, or Bacon, and yet, if these conditions are recognized early, can be prevented from such ultimate results. I must confess that after a stricture has formed at the sigmoid or in the rectum, in the great majority of cases no good can come from the treatment of the stricture *per se*, and recourse must be had to such procedures as those mentioned in this paper. And in this day, when such aseptic surgery can be done in the peritoneal cavity, I see no reason why such attempts as suggested by Dr. Bacon should not be undertaken. But as prevention is better than cure, I will conclude my paper by dealing with the treatment of such conditions as give rise to the necessity of such operations.

The sigmoid flexure is peculiarly liable to local disease. Outside of malignant affections its anatomical arrangement is such, that it is made the receptacle of the fæces, both as the mass is attempting to pass out in the act of defection, and the remaining portion is pressed back by an anti-peristaltic movement. Hence it is no wonder that it is subjected to congestions, inflammations, ulcerations, etc., and these combined frequently establish non-malignant strictures. I have tried to demonstrate in a former article that the flexure was often, I might say commonly, the seat

of impaction by fæces, and the fatality of such impactions sometimes all can attest. In addition to many cases of sigmoid disease that I have already related, I now desire to call attention to but a few:

No. 1. Mr. J., aged twenty-eight. By occupation a civil engineer. About five months ago complained of a slight diarrhœa. He consulted a physician, who gave him the usual remedies for such cases, but the discharges increased, from four or five daily, to twelve or fifteen in the twenty-four hours. His condition growing serious, and his disease not responding to internal treatment, his physician sent him to me, thinking that the cause might be found in the rectum. His diarrhœa had now continued five months and he had lost forty pounds of flesh; no energy, and all appetite gone. An examination was now made of the discharges and they were found to be composed of blood, mucus and pus. Not dysenteric, as no elevation of temperature or pulse occurred at any time. An examination of the rectum revealed an extensive ulceration, beginning about four inches up and extending evidently into the sigmoid flexure. This man gave no history of syphilis. I had him discontinue all internal medication, go to an infirmary and observe perfect rest in bed, first giving him a free purge. I then washed out the sigmoid with hot water. He was put on a special diet and the local treatment begun, which consisted in depositing in the flexure daily one ounce fluid hydrastis diluted with two ounces of water. From the first injection the discharges began to assume a natural condition, and at the end of ten days all mucus, blood and pus had disappeared. In this time his appetite had returned and he began to take on flesh, although on a liquid diet. At the end of two weeks he left for Chicago with directions to inject the sigmoid every alternate day. This case is but a sample of a number that I had to report, but my time being limited, will make this one suffice for the evening.

DISCUSSION.

Dr. H. H. Grant: Could the small bowel be made to do the duty of the rectum in case of anastomosis? Would not the fecal matter block up below where the transfixion was effected? Would it not be better, in other words, to make an artificial annus, as it is now made, for the relief of these conditions?

Dr. J. M. Mathews: I suggested that it might be better than a colotomy, and for that reason suggested that it might be better to anastomose the sigmoid flexure or the colon to the rectum, as practiced by Senn than to attempt the operation suggested by Bacon.

Dr. W. L. Rodman: I think Dr. Mathews has called our attention to a very important matter, that is, flushing the sigmoid flexure. For this purpose I believe the rectal bougie preferable to the tube, as the latter is liable to curve upon itself. I have seen harm result from the use of the tube. I once made a post mortem upon a patient of a medical friend who had been treated by local applications for dysentary through a rectal tube fully eighteen inches in length. The patient died of peritonitis. In making the post mortem I found the belly full of fluid, soap-suds, etc., used in the injections, which had passed out through a perforation of the gut made, I think, by the tube.

## PHILADELPHIA COUNTY MEDICAL SOCIETY.

*Meeting, May 24th, 1893.*

Dr. Mordecai Price presented a Report of Interesting Cases in Abdominal Surgery. (See page 15.)

DISCUSSION.

Dr. Joseph Hoffman: Dr. Price stated that in the cases on which he had operated he had not met with high temperature except in two instances. The question of temperature is an interesting one. In one of the most serious cases of appendicitis the temperature was not markedly high, although there was gangrenous gut and abscess. The pain and tenderness were, however, marked. I have seen a case in a young child where the temperature was abnormally high.

With regard to operation: I am puzzled to decide in what cases operation should be done. I have seen cases in which the condition seemed to be imminent, recover without operation, and I have seen cases apparently parallel die. Where the line is to be drawn between the cases that will recover under medical treatment and those in which operation is required is difficult to decide. Within a week I was called to see a boy eighteen years of age in a second attack. There was high temperature and a mass easily to be made out. The bowels had been bound up, and no relief was afforded by anything that had been done. I put the boy on purgative medicines and within forty-eight hours there was a reduction of temperature, and in another forty-eight hours the abdomen was perfectly pliable and the boy apparently well. I suggested operation, but it was not accepted. Whether or not this trouble will come back, I cannot say.

Dr. Addinell Hewson: I have made some investigations in the dead body with reference to the position of the appendix. I examined some 74 bodies. In this number I found evidence of appendicitis of more or less severe degree in 23 cases. Only one showed that there had been operative interference. The investigation was not made to determine the presence of appendicitis, but simply to obtain anatomical data by which the position of the appendix could be more definitely reached. The position of the appendix varied considerably. In one instance it was in contact with the under surface of the liver. In many instances it was in the cavity of the pelvis. In many it was above the crest of the ileum, and in the majority of cases the base of the appendix was above the inter-iliac line—this is the line drawn from one anterior superior spinous process to the other. I made some notes in reference to other points in connection with the appendix, but they are not germain to the discussion. I merely wish to recall the fact that there were evidences of appendicitis in 23 of the 74 cases.

The results of examinations will be published later in the *Amer. Journ. Med. Sciences.*

Dr. Daniel Longaker: It seems to me that the last case reported is only explicable on the assumption that, as a result of rude manipulation, some focus of pre-existing disease was disturbed, or, if the trouble was not produced in that way, it must have been set up by the production of endometritis and extension from this point. I assume this from an experience that I have had. A woman supposed herself pregnant and introduced a knitting needle into the uterus. She experienced no pain at the time, but in the course of a few weeks there was severe suffering and septic endometritis. Whether or not she was pregnant was never ascertained. The inflammation soon extended and involved the tubes, and in a few weeks there resulted a large tubo-ovarian abscess and a decided attack of pelvic peritonitis. The trouble was promptly removed; but I may say that the endometritis still lingers, and will probably require a second operation, that of curettement. I would ask whether or not this condition exists in the case referred to by Dr. Price.

Dr. James Collins: Regarding the relations of medical and surgical treatment in appendicitis, I am sorry to report that I have seen several patients die in whom I had advised operation, but was overruled by the medical attendant. I have seen one or two saved, but that is such a limited number that I dare hardly speak of it in connection with the number of cases reported to-night. I suspect that it is safe treatment, where the obstruction and symptoms of appendicitis continue after the second day, to consider the advisability of surgical interference, and especially so if there is present a sign not often mentioned, which in the male is pain in the line of the cord and testis. In one or two cases the medical attendant has taken the ground that because there was no high temperature there could not be any very serious inflammation in progress. I have for many years advocated operation in appendicitis, and I have said that I would never let another case where there were evidences of peritoneal inflammation die without operation.

The President, Dr. De Forest Willard: I am glad that Dr. Price emphasized the point of low temperature which is so common. It seems that in these cases the temperature is positively no indication of the severity of the case, and is not to be relied upon unless it is very carefully watched. There are certain cases where, if it can be watched day after day, it then becomes an important element in diagnosis and prognosis.

In common with Dr. Hoffman, we are all seriously puzzled to draw the line between the cases that will recover without operation and those which should be operated upon. This subject cannot be discussed too frequently, and every case should be recorded and thoroughly considered and studied.

Dr. George E. Shoemaker: The point of diagnosis is one of great interest, and those who have had surgical experience with appendicitis should emphasize the fact that there are no signs which are absolutely reliable. Dr. Willard will recall a case which I recently reported, and which he afterward saw, where there was gangrene of the appendix and where there was no tumor; where there was no tenderness in the rectum, and where there was no tympany. The belly was scaphoid, and yet there was gangrene of the appendix, with perforation. I was utterly deceived as to the necessity for operation in a case which occurred several years ago. A German woman of exceptionally good physique, and whom I knew to have no uterine or tubal disease, was suddenly taken with chill and pain in the right iliac fossa. The temperature went up to 104°, and the symptoms persisted for four days. I considered the case to be one of appendicitis, feared pus, and advised operation. I had a consultant who also advised operation. The patient refused and asked to see still another consultant, and in the twelve hours of consequent delay her condition completely changed for the better, the temperature went down and in time she made a complete recovery without operation. Within a few days she passed pieces of tapeworm, which probably had been the exciting cause of the appendicitis. As a contrast to this unexpected recovery, on the very day of my proposed operation a young man died in this city because he had a pint of fetid pus about his appendix, and because one of the most capable diagnosticians anywhere denied its presence till too late. The great majority of cases that I have been called upon to observe have gotten well without operation, because pus did not form. But the attacks recur. This question is one of gravity. A gentleman came to me to-day to know what I would advise in a case which I had seen some years ago with him. The patient then had appendicitis and recovered; but the attacks have recurred, gradually becoming more severe and the intervals shorter. I said that in such a case operation was advisable, but each case must be studied by itself. There are no definite rules, and never will be.

Dr. William M. Welch: I have seen a few cases of appendicitis, and recall some four or five that have recovered without operation. Still I am inclined to think that surgical interference is a matter to be thought of in all such cases. Last summer I saw a case in consultation where I proposed that a surgeon be sent for with a view of considering the propriety of an operation; but the patient positively refused, and after suffering for two or three months recovered, as I believe, perfectly. One of my cases, a child, developed an abscess, which discharged through the umbilicus for a considerable time; but even this was followed by recovery.

You will remember, Mr. President, that a year ago a discussion took place here on this subject, and that the surgeons insisted that an operation should always be thought of, while the physicians held that surgical interference was required only in a small proportion of cases. There was present at that meeting a layman of considerable prominence who told me the next day he was deeply interested in the discussion, as he had recently gone through an attack of appendicitis; that the surgeon who was called in consultation advised operation, while his attending physician opposed it. He said he followed the advice of his physician and is glad that he did so. I mention this to show that recovery from appendicitis may follow medical treatment when surgical interfence is thought necessary.

Dr. James P. Mann: I wish to say a few words in regard to two cases that have come under my notice. One was a physician, a friend of mine, and a man of considerable surgical experience, especially in abdominal work. He simply felt sick, but had no pain and no elevation of temperature. There was a little constipation. A diagnosis could not be made, until, finally, Dr. Wyeth, of New York, inserted his finger into the rectum and found a soft tumor on the right side. He then hazarded a diagnosis of appendicitis. The case was operated on and twelve ounces of pus removed, with recovery.

The second case was that of my son, two-and-a-half years old. He was taken sick in the night and appeared to have a little pain in the abdomen.

The temperature remained normal. The case was seen by Drs. Joseph Hearn, A. G. Hinckle, and Allis. For the first three days there was some obstruction of the bowels, but that passed away under simple treatment. The child seemed to be improving, but at the end of a week he suddenly went into collapse and died rapidly.

The post-mostem showed that there had been appendicitis with rupture and general peritonitis, and all this without any symptoms of appendicitis that could be appreciated.

Dr. G. Betton Massey: I have seen two cases of appendicitis that have led me to certain conclusions in the matter. The first one was a gentleman of prominence in the city, who had been nursed through seven attacks of appendicitis. This man was almost black from the prolonged use of nitrate of silver. Some months after I saw him he died in a recurrent attack.

The second case occurred recently in a young woman. The attack was diagnosed by myself and others as a second attack of appendicitis. I advised the patient to put herself in the hands of a surgeon for operation after recovery. This she did not do. Three months later she had another attack and died. Of course, this is a small number of cases to form a judgment upon, but it leads me to the conclusion that surgery is the best treatment, at least after the second attack—not during the attack but in the interval.

The President, Dr. De Forest Willard: Dr. Welch is in error in intimating that the surgeon, "of course, urges operation." A few years since this subject was discussed independently by two societies, The Association of American Physicians and the American Surgical Association. The consensus of opinion in the surgical society was rather against the operation; that it was an exceedingly difficult and dangerous one, and that it often was impossible to find the appendix; while the physicians strongly advised operation, and the speakers considered it to be perfectly simple, and held that no one would have any difficulty performing it. From my own experience, and I have seen a large number of these cases in the past few years, I am sure that surgeons refuse operation in a far larger number of cases than they operate upon. The surgeon is often obliged to restrain the physician in his desire for operation.

Dr. Price: In my estimation, there is only one treatment for suppurative appendicitis. I do not mean by appendicitis simply irritation of the appendix, but I mean inflammation of the appendix going on to ulceration and rupture. One physician asserted, in the discussion referred to by Dr. Welch, that if all these cases were operated upon there would be 20 per cent. more deaths than at present. The operations of surgeons in this city will positively refute that statement. I can give a hundred cases, in the hands of a dozen men, with not more than ten or twelve deaths. An appendix operation has no business to kill, and the man who cannot find the appendix either does not know where the appendix is, or he has another condition, in which he has no business to hunt for the appendix. If there is an abscess at the head of the colon, with the peritoneum shut off, it should be opened, washed out, and packed, and the patient will get well. No effort should be made in these cases to find the appendix.

With regard to the symptoms of appendicitis, I think that they are plain. If in the first twenty-four or forty-eight hours you find a tumor, that is not appendicitis. An abscess of such size does not form in so short a time. There may be high temperature; that has nothing to do with appendicitis, necessarily. There is an impacted colon and something irritating the colon. The administration of salts, persisted in until free evacuation of the bowel is produced, often cures the patient. If called to a patient with symptoms of appendicitis and you administer a purgative, and, coming back after free purgation, you find the mass and swelling and the patient no better, you have a case of appendicitis every time; you have an abscess forming at the head of the colon. It is your business to cut down and drain that, and if you open the peritoneal cavity it does not matter. If you wash out the peritoneal cavity and put in a gauze drain the patient will recover. When you find a man with a pulse of 170, where a grain of opium, or two or three grains, an hour have been given, with all the symptoms smothered, with a mass in the right

iliac fossa, and a temperature of 97°, respirations reduced to ten or twelve per minute, let him alone. Such a patient is beyond all possible chance of recovery.

We must recognize that all the troubles in the right iliac fossa are not appendicitis. Unless we have positive proof that there is trouble, we should not interfere.

In regard to Dr. Welch's cases. Patients do recover with abscess at the head of the colon; but is that treatment? Because now and then a man falls off a house and is not killed, it does not follow that that is a good way to get down. We have no business to call that treatment. It is our duty to do that which we find best for the patient, and not run the risk of having the abscess break into the colon or other viscera, and matting together of the bowels and crippling the patient for life. A short time ago I saw, in Albany, one of the cases which Alonzo Clark reported as appendicitis cured by opium. The man said to me that he had carried that appendicitis with him ever since. It ruptured into the bladder, and he passed feces for six months. Such cases as this are a proof that we should relieve these cases, and do it early, in order to avoid those fearful accidents which Nature in her attempt to save life, brings about.

I doubt whether Dr. Hoffmann's case was one of genuine appendicitis. There was trouble there at the head of the colon, with inflammation and tumor.

Dr. Musser had one of the most typical cases of appendicitis without rupture that I ever saw. The patient had had three or four attacks every year for several years. Dr. Musser diagnosed appendicitis. In all the attacks, except the last, the patient was relieved by free purgation. Dr. Joseph Price was then asked to operate. The history was clear, the appendix was large and distended with pus. The abdomen was opened and the tubes and ovaries found healthy. The appendix was not adherent and looked well. It was caught with hæmostatic forceps and tied off. On squeezing the removed appendix the nastiest pus could be squeezed out of it.

In the seventeen cases on which I have operated, I did not remove the appendix but twice. The trouble is, that we do too much surgery. A surgical operation for pus at the head of the colon, from any cause, if done in time, should not have 1 per cent. mortality. We have come to the point where there is but one obstructor in appendicitis cases, and that is the general practitioner consultant.

Dr. George I McKelway exhibited a

PORTABLE AND CONVENIENT FRAME FOR TRENDELENBURG'S POSITION.

---

### Flatulent Dyspepsia.

℞ Bicarbonate of soda..... gr. lxxv
Prepared chalk..... ʒi
Powdered nux vomica..... gr. xv
Powd. red cinchona bark..... ʒi

Make 20 cachets.
Sig.—One cachet before each meal.

—*Union Medicale.*

---

### Liniment for Neuralgia.

℞ Chloroform..... 6 drachms
Sulphuric Ether..... 1 ounce
Spirits Camphor..... 3 ounces
Tinct. Opium..... 1½ drachms

M. Sig.—Soak a small piece of flannel with the liniment, and apply over the painful part.

---

Cramps of the Legs in Pregnant Women.—Administer at bedtime five milligrammes of sulphate of copper. This can be administered every night without inconvenience. — *La Gazette Medicale.*

---

For the Night-sweats of Pulmonary Tuberculosis Dr. Ewart (*La Semaine Med in Med. News,*) suggests:

℞ Quininae sulphat.,
Zinci sulphat.....āā gr. ij
Ext. hyoscyami..... gr. j
Ext. nucis vomicae..... gr. ⅓

M.—Ft. pil. j. Sig.—Take at bedtime.

---

### For Paralysis in Lead Poisoning.

ISSUED EVERY SATURDAY

ADDRESS
Care P. O. Box 843, Philadelphia.

HAROLD H. KYNETT, A. M., M. D.,
Editor.

RODERIC C. PENFIELD,
Publisher.

316 = 18 = 20 North Broad Street,
PHILADELPHIA.

**TERMS**:—Five Dollars a year, strictly in advance, unless otherwise specifically agreed upon. Sent three months on trial for $1.00.

**REMITTANCES** should be made payable only to the Publisher, and when in sums of Five Dollars or less, should be made by Postal Note, Money Order or Registered Letter.

**NOTICE TO CONTRIBUTORS**:—We are always glad to receive articles of value to the profession, and when used they will be paid for, or reprints supplied, as the author may elect. Where reprints are desired, writers are requested to make a note of that fact on the first page of the MS. It is well for contributors to enclose stamps for postage, that the articles may be returned if not found available.

SATURDAY, JULY 1ST, 1893.

## EDITORIAL.

### DOES THE AMERICAN MEDICAL ASSOCIATION NEED A MEDICAL JOURNAL?

Within the past few years this question has often arisen, and it now recurs with emphasis greater than ever, since, in the latest issue of the *Journal of the American Medical Association*, the retiring editor attempted to make a plausible explanation for a very bad case.

When we behold the present strength and wealth of the *Journal of the British Medical Association*, we naturally inquire why America cannot maintain a journal its equal or superior. But if we consider for a moment and investigate, the answer is apparent. There is no analogy between the medical affairs of Great Britain and those of the United States. They, as a nation, have state medicine and we have not. England has no medical weekly of importance sufficient to compete with the Association's journal save the *Lancet*, while in America, there are at least a dozen journals of commanding merit. Over the ocean, the government is monarchial and paternal; tenure of office, private and public, has a stability and permanence quite impossible in a democracy.

Great editors are not born or made to order every day. It was only a Wakely who could found a *Lancet*, and before the fortunes of the *Journal of the British Medical Association* were placed in the hands of Ernest Hart, it had a precarious existence, and was given into his charge a forlorn hope. Moreover—there is no use of disguising it—the average respectable and influential American medical weekly is not in sympathy with the full development of the "association journal" idea. Editors and publishers know well that to make it in value and influence proportionate to the mighty nation which it should represent, would in one year, sink out of sight nine-tenths of the journalistic yield of this country. Doctors want to edit journals, and to own them too. Self preservation is one of the strongest in-

stincts of human nature. Can such a journal be made powerful, prosperous and popular without disturbing the interests of vested rights?

It has been well known to those "behind the scenes" that the financial state of the *Journal* has of late been questionable; that in influence and importance it was ever becoming weaker and weaker, is evident to every one.

It may have been in questionable taste for Dr. R. Harvey Reed to have "let the cat out of the bag," yet as a member of the Business Committee he was bound to inform the rank and file of the actual state of affairs. That there was no justification for branding him "a liar, a crank and a fool," because he told the truth and sounded the warning note, is evident by the action of the trustees in retiring the one who employed this intemperate and harsh language.

---

## IN MEMORIUM.—JAMES McCANN, M. D., LL. D.—1836–1893.

Was born fifty-seven years ago in Penn Township, Allegheny County, Pa. His father served under Anthony Wayne in the war for American Independence. In early boyhood he passed his summers working on his father's farm, and the winter months as a pupil of John G. Beatty, who taught him, in addition to the public school curriculum of that time, Latin and the higher mathematics. At about thirteen years of age his father died, when he began teaching school and became a leading member of a local debating society. Even at this early date he was a ready, fluent and earnest talker. Tiring of the monotony of country life, and like the majority of young men of his age, not knowing exactly what to do with himself, he decided upon a mercantile career, and at the age of eighteen came to Pittsburgh, where, after graduating at Duff's College, he spent several years as bookkeeper in a business house. This sedentary life became irksome to him, his health was not good, and acting upon the advice of his physician, who regarded him as a young man of promising talents, he finally decided to study medicine. With this object in view, he, in 1858, entered the office of Drs. Thomas and John Dickson, Sr.

He graduated from the Medical Department of the University of Pennsylvania in 1863, and immediately entered the medical service of the army as assistant-surgeon of the Fifth Pennsylvania Volunteers. He continued in this service until the close of the war, when he returned to Pittsburgh and began the practice of medicine with Dr. W. C. Reiter. Two years later he received the appointment of surgeon to the Marine Hospital, and the connection with Dr. Reiter was soon afterward dissolved.

He was next appointed one of the surgeons of the Western Pennsylvania Hospital, which position he held until a few months ago, when he resigned because of ill health, and accepted the appointment of consulting surgeon. For twenty years he has been one of the surgeons of the Pennsylvania, the Allegheny Valley, and other railroads entering this city.

He was an active and influential member of the Pittsburgh Free Dispensary from its inception, of the Board of Health for many years, of the Allegheny County Medical Society, of the State Medical Society, of the American Medical Association, of the American Surgical Association and of the American Association of Obstetricians and Gynecologists, but owing to ill health he was never able to attend a session of the latter.

In spite of the busy life he led, his ardent love and natural aptitude for teaching led him—in connection with his confreres of the "Mott Medical Club"—to undertake the arduous task of organizing the first medical college in Western Pennsylvania. Into this work he threw all his enthusiasm and devoted to it all his energy and influence. Caring but little for pecuniary reward it was with him a labor of love. In September, 1886, after years of weary and distasteful work, the culminating point of his ambition was attained by his election to the chair of Professor of the

Principles and Practice of Surgery. This position, notwithstanding his failing health, and in defiance of bodily suffering, he filled until a few months prior to his death. At last, his physical endurance being exhausted, his grateful and sorrowing colleagues unanimously nominated him for appointment as "Emeritus Professor," a last tribute to his eminent worth and ability, but before this action could be confirmed by the board of trustees of the University, death had claimed him as his own.

He died a martyr to his profession—a sacrifice upon the altar of charity. His love for it and devotion to it was the direct cause of his death. He performed an enormous amount of work, and it was in the performance of a surgical operation, a work of charity in the Western Pennsylvania Hospital, that he received the fatal shaft from the quiver of the fell destroyer. Had he, like many others, turned aside from charity work and devoted himself strictly to his lucrative clientele, he would be living to-day.

He never ceased to be a student. He was too broad-minded to make a successful specialist. His mental attainments were too great, his studies and reading too comprehensive, his ambition too high for any single department of his profession to permit free scope to his talents. His mind was alert to grasp and tenacious to retain knowledge, which enabled him to easily keep pace with progress and improvement, however rapid, in every department of medical science.

He stood in the front rank of the leaders of the profession. His *savoir faire*, his strong personal individuality, his impulsive and generous nature won him a host of friends in and out of the profession.

His reputation and practice were not limited to his own city, county or State, but were national. His life was one of unceasing toil. There are but few surgical operations that he had not performed. His profound knowledge, rather than his personal magnetism, made him popular with all the members of the profession with whom he came in contact, making him eagerly sought as a consultant, and he never betrayed this trust.

He followed, as strictly as the present state of society will, perhaps, admit, the axiom, "a physician's first duty is to his patient, his second only to himself."

He was in the active practice of his profession from 1863 to 1893—a period of but thirty years, yet in those thirty years he accomplished, perhaps, a task as great, and fulfilled a destiny as rounded and complete as the average practitioner of fifty years standing. A man's life is measured by his works. Judged from this standpoint, although he was but fifty-seven years of age, his death was not premature.

He had faults, but no vices, and his virtues were too many to dwell upon at greater length. By his death his wife loses a loving husband, his children an affectionate father, his colleagues a genial companion and true friend, and his profession a devoted follower. *Requiescat in pace.*

**Morphine and Gastric Secretion.**

Hitzig has noted that morphine administered hypodermicly to a dog is shortly afterward excreted by the stomach, and that, following upon this, there is a marked reduction in the amount of gastric juice secreted, and more especially of its acid constitutant. The cessation of the action of the drug is followed by the secretion of excess of hydrochloric acid. With regard to the effect upon human gastric juice, the case is described of a patient who consumed daily two grammes each of morphine and cocaine, the latter having been resorted to in an endeavor to remove the craving for the morphine. He was treated by gradual reduction of the doses of the alkaloids, but it was not until the morphine was entirely discontinued that the presence of free hydrochloric acid was indicated (*Neur. Centr.*, *B. M. J. Epit.*, *1671,4*).

# CORRESPONDENCE.

## PRESIDENT ROBERTS AND HOMŒOPATHY.

In the Reporter, of May 27th, appears the annual address of Dr. John B. Roberts, President of Philadelphia Co. Medical Society, entitled "Points of Similarity between us and Homœopathic Physicians." President Roberts deserves thanks, and thanks with a big T, for the able manner in which he has handled the subject regardless of the title; it is a masterly exhibition, or even exposé, of the position of the Sectarian Brethren as they are today. For the charming scholarly style in which the subject "is done," the Doctor "takes the cake," and deserves the whole bakery. Dr. Roberts might have gone still farther in his investigations and told "us" of "the Points of Similarity," at the *starting point*, between "us and Homœopathic Physicians."

For instance, regardless of his choice of school, the average student starts in with very little general information about "men and things," and none whatever, of the subject of his choice. He steps into the field, not to investigate but to follow a beaten path, and is ready to believe all that is taught him. If he chooses a Homœopathic School, he is ready to believe that "Regulars," styled "Allopathists," are little short of antiquated, dough-headed murderers, who treat patients according to the rhyme:

> "I purges, I pukes, and I sweats them,
> Then if they die, I lets them."

He is ready to believe that in accordance with "Similia Similibus Curantur" theory the administration of gold will cause a man to be avaricious, and the administration of sulphur cause a man to despair of his eternal salvation, and even long for the "Lake of Fire and Brimstone," if given in sufficient doses; while the proper attenuation of the same will chase out the despair and raise a camp meeting feeling in his bosom. If he sups with the "Eclectics," he has no difficulty in swallowing the "Pap" that both Regulars (here also styled Allopathists) and Homœopaths, are following a metallic route to perdition, and that Eclectics alone "select" their remedies from all proper sources. If he goes to the "Regulars," he is fully capable of taking in, without an effort, the doctrines that Homœopaths and Eclectics are "Ignorant Heretics," to be classed with "Quacks and Tramps." Just in accordance with the class of Professors he falls in with, will he be filled up, more or less, with the gall and bitterness of adverse criticism. So he goes out into the world, armed, he thinks, against both disease and professional foe. The world into which he goes, knowing just as little of the science of medicine as he did a few months ago, hears his ranting and raving, breaks into factions, and believes or disbelieves, some from ignorance, and some from pure cussedness.

Another "point of similarity" the Doctor might have mentioned is the ignorance of the average practitioner of either school of what is taught in the adverse school. Now, as the value of one's opinion, on a given subject, is just in accordance with the perfectness of one's knowledge of the subject, it follows that most of the time neither party knows what they are talking about. Hence, it becomes a sort of "You're a liar" and "You're another" kind of an argument, while the outsider looks on and grins. In view of all this, Dr. Robert's paper is most timely; it shows that the Homœopathic people are coming around to rational medicine because it is rational. He shows that a few, only a few, play Hahnemann, with Hahnemann as the principal character. That many, very many, are content with only a recognition of him as "a has been." The picture is as bad as the "play of Hamlet, with Hamlet left out," and content that the ghost of his Father is left in.

The Doctor's "investigation" is intended by him to illustrate his position, that membership in a regular medical society ought to be open to this class of physicians. He accords, and justly so, to them "courtesy, refinement and large hearted charity." In a communication of mine, published in The Reporter of February 23rd, 1889, I used these words: "We must recognize that there are just

as true gentlemen, loyal citizens and Christians practicing in the other schools as in our own." We can all, at least, respect the Sectarian, who is honestly practicing his belief, just as one can respect a fellow regular whose idea of treatment may differ radically from one's own. Unless, indeed, it is that class, few in number I am glad to say, who still calling themselves "regular," assume the,—"Treat you either way" dodge. A sort of—"you pays your money and takes your choice"—game of therapeutics. No one respects them, though sometimes they are of more than average ability. One of the brainiest practitioners, of my knowledge, in Western Pennsylvania, does all that, and more too, for he poses thusly: "Catharsis, Allopathic, Emesis, Homœopathic, see? so I use a double system, one acting well, upwards, the other acting well, downwards, result, perfection, see?" *Of course*, the patient sees, *they always do*, when that sort of thing is done impressively, and the double system doctor pockets good fees. I don't think Dr. Roberts would care about him, though, in a "regular" way.

While I do not intend this as an illustration of the class of physicians President Roberts presents in his paper, yet I do say that this paper causes one to reflect, thoughtfully reflect, on his *facts* and suggestion in this way, viz: "*Is it honest* to cure diseases by non-Homœopathic methods and contrary to Homœopathic law, and yet *claim Homœopathic credit for the result? Is it honest* to admit that "had not our school drifted away from the practice of forty years ago, it would have been dead and buried long since," and yet give that *same law of cure* of forty years ago, the credit of what that school does by *rational methods* and *regular school therapeutics* to-day? *Is it honest* for a school that uses as "Text Books—the U. S. P.—Woods Therapeutics—Pepper's System of Medicine," as well as those by "Gross, Agnew, Playfair, etc.," to be posing as teaching according to Homœopathic law? "Pepper" recommended as a "Text Book" by "Hahneman College" is enough to cause the shade of the Apostle of Homœopathy to shed bitter tears, even though the "Pepper" wasn't *re(a)d*. That somewhat salty sentence rolled out from my pen before I really caught on to it myself, and it wasn't intended as a *dry* joke either. *Is it honest* for a school to use the brains, scholarship and text books of rational medicine, and at the same time refuse to sit on an Examining Board with that scholarship and examine on those text books? Use the books for the student, and yet insist on *examination* according to *Homœopathic Law. Is it honest?* If it is, then my very good friend Dr. Roberts is right, and we should open the doors of our societies and bid them enter. If it is not honest to forsake the substance and claim credit for the shadow; if it is not honest to forsake Homœopathic Law, while claiming credit for "Similia Similibus Curantur" (as every one who still clings to the name does) then the door should be shut. There is no doubt but that a very large portion of the regular profession are willing to sit down and exchange, gladly, specimens with Homœopathic physicians where sectarianism is by them set aside. Is it not asking too much to throw open the doors of rational medical recognition to gentlemen who while "*practicing it, deny the faith.*" Dr. Roberts is such a genial, good hearted man, to say nothing of his sterling professional qualities, that the Homœopathist who would not *want to consult* with him would be "hard-hearted and white-livered" indeed, and the doctor is just enough and broad enough to be willing to help even a "Thompsonian" to improve his "number six." However, would it not be as well to wait until the gentlemen of "Similar Points" get to the broad "Similar Point" that Dr. Roberts has reached, and *want to come in.* I am sure that they can, just as soon as they reach a "Similar Point" of being not sectarian, but Fellow Craftsmen for the *common good.*

In the meantime I think the position of the regular profession towards Dr. Roberts' paper will be this "That we thank him for the publication, for its information and general blessedness, regardless of his suggestion."

S. S. Towler, M.D.,

# THE LIBRARY TABLE.

## BOOK REVIEWS.

*A Standard Dictionary of English Language.* Funk & Wagnalls Co., 18 and 20 Astor Place, New York.

We have examined the sample pages of the "Standard Dictionary" and are convinced that the work will prove of invaluable service, and will take a place in the highest ranks of works of the kind. It contains the best points of most other similar works with some distinguishing features of its own of greatest value. Among them, we note first that the etymology of words is placed *after* the definition, that in the definition of words the most common meaning is given first, which is the order of practical common sense. That in the pronunciation of words, the scientific alphabet recommended by the American Philological Association is used. That the quotations used to verify or illustrate the meaning of words are located by author, book, page and edition. That disputed pronunciations and the spellings are so given as to furnish a consensus of the best judgment of the English speaking world on all disputed words. That a serious and successful attempt has been made to reduce to a system the compounding words. That obsolete, foreign, dialetic slang words are given places only to be sought for in a general English dictionary, while the vocabulary is extraordinarily rich and full, surpassing any other dictionary.

A marked feature is the pictorial illustrations, nearly 5000 in number, including several full page groups in colors made in the highest style of the art by the Messrs. Prang.

We note the editorial staff comprises a number of the most eminent specialists in their various departments, and their work seems to be extraordinarily well done. For instance, in all matter pertaining to our medical profession, the dictionary is full, accurate, and up to date. The features of this dictionary will commend it to students and scholars. The work will prove of superior convenience and includes an extraordinary amount of material not found in the ordinary dictionary, and will quickly become the "standard" in reality as well as in name.

---

*The Surgery and Surgical Anatomy of the Ear.* By Albert H. Tuttle, M. D. *Physicians Leisure Library,* Geo. S. Davis, Detroit, Mich., 1893.

Works like this one should be of immense value to the busy surgeon, as it furnishes in a reliable and compact manner, the topographical landmarks of the temporal bone after giving us five chapters, four of them clearly describing the surgical treatment of the ear, beginning with the external canal and concluding with the brain lesions so often resulting from diseases of the middle ear. The first chapter is devoted to the anatomy of the ear. In describing the diseases of the external canal, the author does not mention atresia of the canal, a condition by no means rare and calling for surgical intervention. He very wisely considers suppurative inflammations of the brain and its meninges, except those of tuberculous or traumatic origin, to be associated with middle ear disease. In the chapter on the mastoid and its operations, the author considers Schwertze's indications, eight in number, as the most valuable in determining the advisability of an operation; early operation is advised in all cases as tending to lessen the inflammatory process and rarely terminating fatally if early performed. Dr. Tuttle also furnishes a ready means of refering to the literature of many authors on the anatomy and surgical treatment of the ear.

The scholarly presentation of this little work should make it welcomed both by the general surgeon and aurist; it is, however, for its sections of the temporal bone and topographical description that Dr. Tuttle has furnished us so reliable a guide. It may be said of this little work, that it embodies in a condensed form a large part of the most recent contributions on the surgery of the ear.

---

*The Diseases of the Nervous System.* By Dr. Ludwig Hirt, Professor at the University of Breslau. Translated with permission of the author by August Hoch, M.D.; assisted by Frank R. Smith, A M. (cantab), M.D., with an introduction by William Osler, M.D., F.R.C.P., Professor of Medicine in the Johns Hopkins University, etc. With 178 illustrations. Pp. 683., New York: D. Appleton & Co., 1893.

In his "Introductory Note" to this English translation of Professor Hirt's valuable work, Dr. Osler informs us that the idea of having it translated was due to Dr. Weir Mitchell calling his attention to its exceptionally good arrangement and thorough description of the nervous system, and all who read this translation must duly appreciate the appearance of another work which manifests so large an amount of research and personal observation in this class of diseases.

The book has three principal divisions: (1) Diseases of the Brain and its Meninges, including those of the Cranial Nerves. (2) Diseases of the Spinal Cord, and (3) Diseases of the General System.

After treating of diseases of the meninges of the brain, no less than 128 pages are devoted to a lucid and comprehensive description of the diseases of the cranial nerves. The author does not discuss one here, one there, and the peripheral nerves of the spinal cord partly in one place, partly in another, according as he is dealing with their motor or their sensory disturbances, but he speaks of the former and of the latter in the order that their anatomical position would indicate.

A somewhat novel arrangement of the subjects dealt with has been adopted. For instance, tabes dorsalis and dementia paralytica are placed among the diseases of

the general nervous system, instead of in the sections on diseases of the cord and diseases of the brain respectively. As Dr. Osler justly remarks "the fact which makes the work of value to the teacher, the student, and the practitioner is the graphic description of the anatomy and symptomatology of the different diseases. Where all is so good it is invidious to select, but the chapter on tabes is an illustration of our author's lucid and, at the same time, thorough treatment of his subject." Whilst believing that it is possible to cure tabes of lentic origin, he concludes the question of prognosis by saying "On the whole, one can say that out of 250 tabetics one has a chance of regaining his previous health."

As to therapeutics, he considers that although syphilis is at the bottom of many instances of tabes, an anti-syphilitic treatment is only admissable in a very small number of cases. Of internal remedies, silver nitrate, ergotin and physostigmine have the preference, in addition to which electrical treatment may yield excellent results in recent cases. He speaks most favorably of the excellent general faradization advised by Beard and Rockwell, and the faradic brush applied to the back as recommended by Rumpf.

In a large number of cases the cold water treatment has been found extremely beneficial, but he emphatically warns the practitioner against the use of warm or hot, as well as steam and sweat baths. The results of massage, he says, are not satisfactory and in relating his experience of the "Suspension" treatment of 115 patients, he states that in no single instance was he able to note any marked or lasting improvement, and the impression which he himself has gathered is, that "suspension" will be in vogue for a time, only to fall again into complete oblivion. The same candid spirit pervades the expression of opinion as to the use of remedies in other diseases of the nervous system. The treatment of myxœdema is omitted, this apparent omission is probably due to the fact that the original work is now four years old.

The excellent illustrations, which are most of them new, faithfully elucidate the text and greatly add to the attractiveness of the work. We regret that our space will not permit us to dwell further upon its contents, but we confidently recommend it to the praetitioner as a faithful guide in the study and treatment of nervous diseases.

---

*Materia Medica and Therapeutics.* In two vols. By Jno. V. Shoemaker. The F. A. Davis Co., Publishers.

Of books on therapeutics there seems to be no end. A book that meets a want or fills a place in medical literature should either say something that others do not say, or should say she oft repeated in much better styyje than has been done by anyone else. This work does neither, therefore, it does not fill a long felt want. If we did not have two or three very excellent works on this subject, Shoemaker's book might be hailed as a valuable tontribution. But the market is glutted with two very able English works and two most excellent American ones. It is true this work is not without some excellent points; yet it blemishes far outnumber its good qualities-

The great value and importance of the imponderable agents such as heat, electricity, hypnotism, massage, rest and the like are very ably, fully and clearly set forth in the first volume, and if the auther had stopped with the first volume his work would have been both unique and useful. The second volume is taken up with drugs and their application.

Due attention is given to the new remedise such as the coal tar preparations. Animal extracts are not even ignored. For this Dr. Shoemaker deserves great credit, but in the discription and application of the more familiar remedies there is too much accepted from others and too little of the author's own experience to give an air of authority to what is said. When antipyrine is recommended for typhoid fever, one is prone to look upon the work as an unsafe guide to the inexperienced.

For the beginner, the work is not practical enough, and for the experienced and scientific physician there are other books that are much better for his library or office table. It might pay any one to purchase the first volume, but the second one would last a long time in the hands of even the most omnivorous reader.

---

# CURRENT LITERATURE REVIEWED.

---

THE AMERICAN JOURNAL OF OBSTETRICS for June. Dr. Paul F. Munde contributes an article on

**Abdomino-pelvic Fistula after Celiotomy and Laparotomy; its Prevention and Treatment.**

The author comes to the following conclusions:

1. The formation and persistence of abdomino-pelvic sinuses after celiotomy and laparotomy should be prevented by all the means at our disposal.

2. Such sinuses cannot always be prevented, no matter how careful we are.

3. A certain number of early, moderate cases may heal under appropriate treatment, and even a few old cases may recover after operation.

4. Celiotomy, or the opening of the abdominal cavity, is usually not necessary or beneficial in treating these sinuses, unless it

can be distinctly shown or suspected with good reason that the focus of suppuration can be reached only in that way.

5. Through drainage into the vagina, whenever practicable, forms the best method of curing deep sinuses.

6. In some cases, where the other methods, medical and surgical, have failed, and where the general health is fair and the sinus gives but little inconvenience, it is justifiable not to subject the patient to the risks and uncertainty of an abdominal section (celiotomy), but to advise her to "let well enough alone" and keep her sinus so long as she can live comfortable with it.

Dr. Andrew F. Currier contributes a paper on "Septicemia and its Treatment with Oxygen." The author reports two cases, in one of which it was believed that the oxygen repeatedly warded off impending death. In the second case, while it is believed the oxygen delayed the fatal issue, it was powerless to overcome the advancing sepsis. The only ill effect which the author has ever seen in its use, consists in pain referred to the region of the stomach, probably due to swallowing the oxygen, which may have been administered under too great pressure.

Dr. Charles J. Cullingworth discusses the subject of

**Retention of Menstrual Fluid, in Cases of Bicorned Uterus, from Uni-lateral Atresia of Uterus or Vagina.**

The author reports a case where the tumor was thought to be a suppurating cyst outside the uterus and a section undertaken for its removal. At the operation, the true condition was discovered and the retained fluid evacuated *per vaginam*. The author states that it would have been impossible to have arrived at a correct diagnosis without abdominal exploration. The two great dangers of the vaginal evacuation of the retained fluid are septicemia and the rupture of a distended Fallopian tube. Both dangers can be overcome, the former by strict antisepsis, and the latter by slow evacuation of the accumulated blood, so as to minimize the risk of exciting reflex muscular contractions. In the event of a rupture of a tube, the abdomen should be promptly opened, the peritoneal cavity cleansed, and the ruptured tube removed. The report includes a number of similar cases reported by other observers, and is illustrated by a cut representing the malformation described in the paper.

Dr. H. J. Boldt discusses

**The Operative Treatment for Myo-fibromata of the Uterus.**

He states that he has been unable by means of electricity, to diminish the size of the tumor in any case, though in a number of instances the symptoms caused by the growth have been relieved—that is the pain and hemorrhage; in others again, the treatment was not only negative, but the patients gradually became worse. He would however, sanction operation in cases of ordinary interstital growths, only after the current had been tried. He warns against the danger of producing suppuration in the tumor by means of the current. If a myomatous uterus in small enough to be removed per vaginam *in toto*, vaginal hysterectomy then is the operation of choice, provided other measures fail of relief. If an abdominal operation is necessary, the neoplasm should be removed by enucleation, when possible, the bed being sewn up with buried catgut sutures. Constricting the cervix with an elastic suture during enucleation he regards as bad. When the body of the uterus must be removed along with the tumor, no method of treating the stump has given as good results as the extra-peritoneal. Personally however, he favors the intra-peritoneal method, and regards Martin's method as ideal. He uses nothing but catgut for the suturing and tying, except in closing the abdominal incision. In the intra-peritoneal treatment, secondary hemorrhage plays an important role in causing death. This need not be feared if the ligatures are properly placed in complete hysterectomy. The main cause of death in complete hysterectomy is shock or extreme anemia, and for that reason he has not entirely given up the extra-peritoneal treatment. The paper gives the report of twenty-one cases operated upon.

Dr. R. Stansbury Sutton discusses the

**Elastic Ligature in Supra-vaginal Hysterectomy.**

The author prefers the extra-peritoneal treatment of the stump because statistics show that this is the better method. The author regards rubber as the ideal substance for the composition of the constrictor for the compression of such tissue as the cervix. He has abandoned the wire nœud on account of the danger from hemorrhage unless the wire is constantly watched and tightened. The rubber constrictor is turned twice about the cervix, underneath the transfixing pin, secured by a double knot, behind which a heavy silk ligature has been securely tied, and closely in front of which a pair of lock-handled forceps grasps the free ends of the ligature. This method is safe against hemorrhage under all circumstances. There is no depending upon an assistant, nurse or self to tighten the ligature; it follows up the shrinking pedicle painlessly and effectually. The primary dressing may remain on the pedicle from nine to thirteen days without any disturbance whatever. During the three years in which he has used this ligature, he has not found a single objection to it, and his hysterectomies have given him no more trouble than his ovariotomies. The paper is illustrated with cuts showing the method of applying the ligature.

Dr. Howard A. Kelly describes what he considers to be the "Best Needle Holder," giving a cut of the instrument described.

Dr. Henry C. Coe discusses the "Internal Migration of the Ovum," reporting a case of repeated ectopic gestation possibly supporting the theory. The paper is illustrated with a cut showing the conditions described in the paper.

This issue also contains the address of Professor Theophilus Parvin to the American Gynecological Association, in which the author urges the necessity of the chairs of

gynecology and obstetrics in our colleges being filled by one man and not divided as is the usual custom. This number concludes with a memorial notice of the late Dr. Charles Carroll Lee.

LANPHEAR'S KANSAS CITY MEDICAL INDEX for June. Dr. Frederick P. Henry contributes a paper on the

**Treatment of Pulmonary Tuberculosis.**

Cod liver oil is given the first rank in the remedies advised by the author. Cod liver oil cannot be retained, or if retained is of very little value, in the cases with febrile symptoms. In such cases, he advises the use of morrhuol. Another drug that is useful is arsenic. Alcohol he considers of doubtful value, though it is possible that, in moderation, it may favor the cicatrization of tubercular deposits in cavities. He is of the opinion that the hypophosphites of soda and lime possess no advantage over the phosphates, as they probably undergo oxidation in the stomach. Glycerin may be prescribed in place of cod liver oil to those with whom the oil does not agree. Iron is advised for the anæmia that so constantly accompanies phthisis, but the author thinks that it is of no use when there is febrile movement. In afebrile cases, it may assist greatly in maintaining the general state of nutrition. For the cough, he considers hydrocyanic acid to be one of the best drugs and, when this alone will not suffice, a little morphia may be added. Iodine, carbolic acid and creasote, by inhalation, are of service in allaying the cough, as is also the well known solution of Dobell. For hæmoptysis, the drugs on which most reliance is to be placed are ergot, sulphuric and gallic acids. The old-fashioned remedy of salt he has also found useful. Dry cupping of the affected side and hot foot-baths are useful as derivatives, and, if the bowels are constipated, a purgative should be administered. Night-sweats are controlled by means of atropia. He has used picrotoxin, though of late he has used agarcin with much benefit and speaks highly of it. It should be given in doses of one-tenth of a grain, combined with a grain or two of Dover's powder.

Dr. M. B. Ward, in an article on "Pyometra," reports a case in which operation was refused by the patient till in extremis. At the section the uterus was found to be completely necrosed, with the walls as thin as paper. Total extirpation of the uterus was performed but the patient died. Hysterectomy he regards as the only treatment for the condition.

Dr. Edward A. Lee, in an article entitled "Preventive Treatment after exposure to Gonorrhœa; and Treatment of the Disease," advocates the irrigation of the urethra for two or three minutes at a time, and repeated once or twice, with a bichloride solution of 1–10,000, or 1–20,000. At the same time, the glans-penis, prepuce and body of the organ should be bathed in the same solution, or one of 1–6,000 or 1–8,000. This, he states, will prevent many cases from developing, provided they be seen within a few hours after exposure. After the disease has been in progress for two or three days, he prescribes salines and copaiba, internally, with injections of bichloride 1–10,000 or 1–20,000 repeated three times a day and followed immediately by the injection of a solution of sulphate of zinc with bismuth.

Dr. J. F. Binnie contributes a paper on "Gradual Auto-inoculation as a Factor in the Production of Immunity from the Effects of Septic Infection."

Dr. Emory Lanphear reports a "Case of Sacro-iliac Disease with Immense Distention of the Abdomen with Pus—Laparotomy—Cure." The remaining articles in this issue: "A Method of Operating About the Face by which but Little Blood Enters the Mouth," by Dr. W. W. Keen; "Amputation at the Hip-Joint—Tumor Near the Sub-clavian Vessels—Operation on the Fifth Nerve," by Dr. John B. Deaver; "Metatarsalgia (Morton's Painful Affection of the Foot)," by Dr. S. K. Morton; were read at the meeting of the Philadelphia Academy of Surgery on March 6th, 1893, and appeared in the MEDICAL AND SURGICAL REPORTER for May 13th, 1893.

## NEWS AND MISCELLANY.

### American Electro-Therapeutic Association.

The third annual meeting of the American Electro-Therapeutic Association will be held in Chicago, September 12, 13 and 14, at Appollo Hall, Central Music Hall Block.

Members of the medical profession interested in Electro-Therapeutics are cordially invited to attend.

AUSTIN H. GOELET, M.D., Pres.
MARGARET A. CLEAVES, M.D., Secy.

## ARMY AND NAVY.

U. S. ARMY FROM JUNE 17, 1893, TO JUNE 24, 1893.

An army retiring board having found Major John O. Skinner, Surgeon, incapacitated for active service, the extension of leave of absence on Surgeon's certificate of disability, is further extended until further orders.

Leave of absence for two months, to take effect on or about July 15, 1893, is granted 1st Lieutenant Benjamin Brooke, Assistant Surgeon, U. S. Army.

Leave of absence for one month and twelve days, from August 1, 1893, is granted Captain Charles E. Woodruff, Assistant Surgeon.

1st Lieutenant Harry M. Hallock, Assistant Surgeon will, on July 6, 1893, proceed to Griffin, Georgia, and report to Captain George G. Greenough, 4th Artillery, for duty in connection with the encampment of State troops at that place.

1st Lieutenant, J. D. Glennan, Assistant Surgeon, now at Fort McIntosh, Texas, will report to the commanding officer 3rd Cavalry, to accompany Troop I of the regiment to Fort Sill, O. T.

℞ Ext. Sumbul . . 1 gr. | Ferri Sulph. Ext. . . 1 gr.
Assafœtida . . . 2 gr. | Ac. Arsenious . . 1-30 gr.

"I use this pill for nervous and hysterical women who need building up." This pill is used with advantage in neurasthenic conditions in conjunction with Warner & Co.'s Bromo-Soda, one or two pills taken three times a day.

### Pil. Lady Webster.
(WM. R. WARNER & CO.)

℞ Pulv. Aloes . . 2 gr. | Pulv. Rose los . . . ½ gr.
" Mastic . . ½ gr. | M. ft. one pill.

Lady Webster Dinner Pills. This is an excellent combination officinally designated as Aloes and Mastich, U. S. P. We take very great pleasure in asking physicians to prescribe them more liberally, as they are very excellent as an aperient for persons of full habit or gouty tendency when taken in doses of one pill after dinner.

### Pil. Digestiva.
(WM. R. WARNER & CO.)
A VALUABLE AID TO DIGESTION.

℞ Pepsin Conc't . 1 gr. | Gingerine . . . 1-16 gr.
Pv. Nux. Vom. ¼ gr. | Sulphur . . . . . ⅛ gr.
IN EACH PILL.

This combination is very useful in relieving various forms of Dyspepsia and Indigestion, and will afford permanent benefit in cases of enfeebled digestion, where the gastric juices are not properly secreted. As a dinner pill, Pil. Digestiva is unequalled, and may be taken in doses of a single pill either before or after eating.

### Pil. Antiseptic Comp.
(WM. R. WARNER & CO.)
EACH PILL CONTAINS

Sulphite Soda . . 1 gr. | Powd. Capsicum . 1-10 gr.
Salicylic Acid . . 1 gr. | Concentrated Pepsin 1 gr.
Ext. Nux Vomica ⅛ gr. | Dose—1 to 3 pills.

Pil. Antiseptic Comp. is prescribed with great advantage in cases of Dyspepsia, Indigestion, and Malassimilation of Food. TAKE NO SUBSTITUTES.

# Mellin's Food
## For Infants and Invalids.

A SOLUBLE DRY EXTRACT of Barley Malt and Wheat, for addition to Fresh Cow's Milk.

Prepared upon the principles advanced by the eminent chemist, Baron Justus von Liebig.

EXPERIENCE — the supreme test — has absolutely proven that the best solution of the problem of infant feeding was made by LIEBIG, and that MELLIN'S FOOD prepared with milk is the nearest approximation to, and is the BEST SUBSTITUTE for, Mother's Milk which has ever been devised.

### THE PALPABLE AND MOVABLE KIDNEYS.*

PAUL HILBERT.

During the year 1889, Israel called attention to palpation of healthy and diseased kindeys, placing stress upon those methods which give definite ideas about the size, the form and position of the kidneys under normal or abnormal conditions. Palpation of the kidneys is performed with both hands, the patient either standing, lying on the back, side or knee-elbow position. As a rule, the back is preferred by both patient and doctor. In palpating the right kidney, the physician stands to the right of the patient, the left hand under the loins immediately behind the last rib, while the right hand, placed opposite the anterior surface, exerts a gradually increasing pressure. In this manner the organ is frequently brought between the fingers of both hands. If this method cannot be carried out successfully, the examination on the side is the next preferable, or the patient may be examined standing, the body slightly bent forward.

Israel has concluded from his studies that every kidney can be partially or entirely palpated, and recognizes a motion induced on the normal kidney by the respiratory movements.

Kuttner, under the direction of Ewald, in the polyclinic of the Augusta Hospital, of Berlin, made a careful study of this subject and, in the course of eight months, had collected one hundred cases in which the kidneys could be palpated. In opposition to Israel, Kuttner maintains that every kidney which shows in palpation a tendency to motion during respiration should be regarded as pathological. In order to aid in deciding this question, the author has made a careful study of one hundred cases, giving a table which represents the grade of mobility, and if right, left or both were affected. He defines the three grades of mobility as follows: First grade of mobility: the lower portion of the kidney can be felt to about its middle. This he names ren palpabilis.

Second grade of mobility: the entire kidney can be felt between the fingers, known as ren mobilis.

Third grade of mobility: the entire kidney can be felt and pushed upwards at will, and he names this ren migrans.

This classification may lead the reader to think that the author regards the floating kidney, or ren migrans, as the highest grade of movable kidney, which, with truth, may be accepted, not, however, in the sense of Litten, who believes that the floating kidney is always of congenital origin; this view has never been demonstrated with certainty, either clinically or anatomically.

It is a well-known fact that movable kidneys occur more rarely in men than in women; this is also true of the first grade in the classification. In order to prove this, the author states that he served for

*A lecture read before the Society of Wissenschaftlitche Heil in Konigsburg i. Pr. Translated by M. B. Werner, M. D.

more than a year in the polyclinic on the male side and found but few cases of palpable kidney.

The hundred cases which I have collected have chiefly occurred among women. The frequency in which palpable kidneys can be found among women is shown by the fact that the first fifty cases were seen during the space of two months (May 28 to July 28, 1890); during this time 435 women were treated at the Polyclinic. The author was able to examine but half the number, say about 200 to 250, which has led him to conclude that palpable kidneys among women stands as 1 to 5.

The recognition of the first classification, rens palpabilis, can be aided by inducing the patient to take deep respirations. During inspiration the kidney usually descends and then can be easily felt by the examining hand, while during the act of expiration it ascends beyond reach. This mobility during respiration of a normal kidney the author has felt distinctively 95 times, twice in a lesser degree and three times it was impossible to feel it. He, for that reason, is inclined to believe with Israel that the respiratory movement of the kidney is physiological and not, as Kuttner insists it to be, pathological.

In the 100 cases examined, 65 were found of the right kidney, and 35 cases in which both kidneys were palpable. Forty of the 65 belong to the first grade, 25 to the second grade. The first grade of mobility was found in both kidneys 8 times, and 9 times of the second grade. In 17 cases the entire right kidney could be felt, while the lower portion of the left could be barely outlined. There was but one true case of floating kidney among the hundred. In this patient the left kidney was easily palpable.

In all these cases there were none found in which the left kidney was alone displaced.

The author has added a table in which he has particularly studied the age of the patient and the three classifications. This table states that in patients between the years of 20 to 40 the kidneys are most easily palpable; that they occur most among women who have never been pregnant. These statements coincide with those of Kuttner. In all cases an examination of the urine for albumen gave the following results: in 9 cases there was but small amount of albumen present; in 5 larger amount. This makes about 14 per cent. of the cases which contain albumen, and in comparing with other patients at the Polyclinic suffering from other diseases than that of the kidney, the author drew the following conclusions:

That abnormal motility of the kidney will produce pathological changes and secretion of urine which may lead to albuminuria.

One patient with ren mobilis of the right side and ren palpabilis of the left side presented, aside from the symptoms of acute nephritis and large quantities of albumen in in the urine, cylindrical casts and blood. The author was unable to find any changes in the form or consistence of the kidneys after the patient's recovery, such as have been observed by Litten and Israel. The author cannot add anything new to the causes which can lead to greater mobility of the kidney. Repeated pregnancies can only, in his estimation, produce as much influence as Landau assumes. Frequently carrying heavy loads or curvature of the spine has been regarded as a cause for dislocation of the kidneys.

The author found in 8 cases a descent of the lower anterior border of the right lung; the same existed of the liver in 4; inguinal hernia in 2; prolapsus of the vaginal walls once. In three women it was possible for him to locate by palpation both kidneys, liver and spleen, although there was no enlargement of any of the above-named organs. In two of these he found, in addition, a large prolapsed stomach reaching below the umbilicus. These cases may be classed, in all probability, with those described by Glenard under the name of Enteroptose.

Bartels and Muller-Warnick have described the connection between movable kidneys and diseases of the stomach; explaining their theory that by traction of the movable kidney, a compression of the duodenum, and through this dilatation of the stomach. Litten has explained it in the opposite, declaring that the dilatation of the stomach is the primary affection, while the dislocation of the kidney becomes secondary. These theories have, however, become questionable, and Litten has forsaken his theory entirely. Kittner, on the other hand, has called attention to the frequency of the presence of enlarged and displaced stomach in connection with

movable kidneys, claiming that in 89 cases in which he distended the stomach, he found an enlargement, perspectively a prolapsus, 79 times. This number seems to the author to be questionable, since, among his 100 cases, in which he frequently made use of distending the stomach, he found but 17 in which he could demonstrate enlargement or prolapsus. A question now comes—if and how much pathological importance can be attached to the palpation of kidneys?

In order to arrive at some definite conclusions, the author studied, in each case very thoroughly, the subjective as well as objective symptoms. After the diagnosis had been made, seven patients were found who had suffered absolutely from the mobility of the kidneys; 8 in which other diseases were present, anemia, tuberculosis. etc., who complained, however, subjectively, only of the movable kidney. This brings the percentage down to 15.

It has been known for some time that floating kidney, or even the second grade, ren mobilis, may give rise to serious changes, either by dragging on the ligaments or by flexure of the vessels or ureters. The author does not conclude that these conditions arise from pathological changes, but that the cause may be sought within the physiological boundaries which often cause abnormalities.

Therapeutically the author recommends certain bandages, or a corset extending to the pubes, which will in a measure produce artificial abdominal walls.

# CLINICAL LECTURES.

## QUINSY OR PERI-TONSILLAR ABSCESS AND ACUTE FOLLICULAR TONSILLITIS; THEIR DIFFERENTIAL DIAGNOSIS AND TREATMENT.

DR. GEORGE M. LEFFERTS.*

GENTLEMEN:—When a sore throat is due to a phlegmonous inflammation it attacks the tissues somewhere about the tonsil, but not the tonsil itself. Here at once we strike at the root of the popular idea that in quinsy sore throat the abscess occurs in the tonsil. It does not. In quinsy sore throat, the favorite seat of the phlegmon is in the tissues just in front, just above and to the outer side of the tonsil; or, in other words, just behind the anterior pillar of the fauces. The phlegmon, starting in this locality, invades the tissues about the tonsil—the anterior pillar of the fauces and the connective tissue behind and above the tonsil. Its next most frequent locality, but much more rare than the other, is behind the tonsil in the posterior pillar of the fauces. In the connective tissue of this part the phlegmon makes much slower progress and is never as large as in the first form. There will be œdematous infiltration and swelling, and the phlegmon will extend down the lateral pharyngeal wall, and it may eventually point as low down as the mouth of the œsophagus, the last place you would look for it to point. The third form is the still more rare. Here the phlegmon locates itself in the groove behind the tonsil, between the two pillars of the fauces. Here also the phlegmon has nothing whatever to do with the tonsil, but the abscess penetrates into the tonsil and opens into one of its crypts. Such an abscess will discharge itself unexpectedly, and you may never know where it was located or how it discharged itself. This phlegmonous inflammation will probably locate itself in eighty per cent. of the cases in the first locality mentioned.

These are the three localities in which you will find a peri-tonsillitis. In the case before us, the phlegmon certainly looks as if it were in the tonsil, for the tonsil is displaced and swollen, but in reality it is a case of peri-tonsillitis.

Now, ordinarily, the exciting cause is a cold, and the predisposing causes are just such large, ragged, irregular tonsils as you

*Professor of Diseases of the Throat and Nose, College of Physicians and Surgeons, New York.

see in the drawings before you. The open mouths of their crypts seem to invite infection. In perhaps eight cases out of ten, the rheumatic diathetis will be the predisposing cause. I know very well that there are cases of idiopathic peri-tonsillitis, where the tonsil is scarcely swollen appreciably, and where there is no history of rheumatism or of exposure, and yet quinsy sore throat develops; but these cases are decidedly rare. Where peri-tonsillitis occurs and recurs, Spring and Fall, year after year, in the middle-age—not in children or old people—you will find that the subjects are almost always rheumatic.

In our patient here, the tonsils have a deep bluish-red color, which involves not only the tonsils but the parts about the tonsils; the soft palate is congested as far up as the hard palate; the anterior pillar of the fauces is crowded forward, œdematous and of the same bluish-red color. The other side shows only the bright red color of acute congestion. The tonsil is pressed forward to the median line and you see the open mouths of a number of the crypts. In this acute, hyperæmic swelling, and this bluish-red color, and the displacement of the tonsil you have the characteristics of quinsy sore throat or peri-tonsillitis.

The symptoms to which this condition gives rise are most marked and painful, and I know of no affection of the throat in proportion to the grade of the inflammatory action, which can give so much pain and discomfort as a quinsy sore throat. In protracted cases, where the pus forms low down in the pharynx, or in the posterior pillar of the fauces, the tissues here being denser, the physician is compelled to watch the gradual approach of these abscesses to the surface without being able to give much relief to the patient's suffering. These cases recur regularly every Fall and Spring until the patient reaches that period of life when the affection disappears of itself. The pain is deep-seated and lancinating at first, but soon becomes throbbing and agonizing, and to the patient who has had a quinsy sore throat is a positive indication that another attack has begun. Soon deglutition becomes absolutely impossible, and respiration is impeded because the fauces are blocked up by the hypertrophied and swollen tonsil. The pain is constant and radiates toward the ear of the affected side; the tongue is swollen and coated; the saliva constantly dribbles from the corner of the mouth, partly because he cannot swallow the saliva and partly because there is an increased secretion of the saliva. The patient cannot lie down and sleep for fear of suffocation, and he cannot eat on account of the pain and obstruction; he can scarcely speak; he is worn out, wearied, nervous and apprehensive. To the experienced eye, this picture is in itself sufficient for a diagnosis. I know of no affection of the throat which can simulate quinsy or peri-tonsillar abscess.

I pass on now to the second form of acute tonsillar disease—acute follicular tonsillitis. This is a very common form of acute disease of the tonsil; it is an easy one to study and understand, and an easy one to treat, but there are certain practical points to which I must ask your attention.

First, then, what is an acute follicular tonsillitis? To the best of my belief today, we are dealing in acute follicular tonsillitis with a germ disease, with a blood poison which has its local manifestation in the tonsil. I believe that if certain predisposing conditions exist—for instance, large, ragged, hypertrophied tonsils—a simple, catarrhal imflammation of the throat may be sufficient to make the soil favorable for the reception of that little germ which comes through the air, and entering the open mouths of the follicles, finds a lodgment there, and creates there a croupous inflammation which is the characteristic of follicular tonsillitis, and also gives rise to a blood poison which produces a marked constitutional disturbance of which I shall presently speak. Or it may be that the germ enters the blood and sets up there those poisonous changes which produce again the constitutional symptoms, and finally, produce the local manifestations in the throat. At any rate, please bear in mind that I consider it to be a germ disease. Although this germ has been eagerly sought for by competent microscopists, it has not been discovered, and we simply infer its existence from the clinical phenomena which this disease presents.

As I have said, a croupous inflammation is established in the lining mucous membrane of one or more follicles, and blocks up the follicles, and this obstruction is as-

sisted by blood corpuscles, bacteria, foreign bodies and the like. The follicle having become filled, its contents overflow, as it were, around the mouth of the follicle in the form of a whitish, ovoid, clean looking little mass. A number of these masses may become confluent, giving rise to a larger pseudo-membrane; or they may remain separate, and the tonsil will then appear to be dotted over with these whitish follicles. Both tonsils are usually affected in follicular tonsilitis.

The constitutional symptoms are marked. There is a decided elevation of temperature; in the adult, the temperature not uncommonly reaches 101° or 102° and in children it is not unusual to find a temperature of 104° or 105°. This fever is associated with a rapid, tense pulse, extreme lassitude and a general aching of the whole body. During the first twenty-four or thirty-six hours there is profound prostration, with marked febrile movement. After awhile deglutition becomes difficult and, if you examine the throat at this stage, you will see the little white points appearing on the surface of the tonsils. As they grow, the urgency of the symptoms disappears. The disease runs its course in from five to seven days, but the marked constitutional disturbance only lasts for about forty-eight hours.

How shall you make the differential diagnosis between a follicular tonsillitis and diphtheria? You are constantly called upon to do this, off-hand, at once, and absolutely. Let me say frankly, that there are many cases in which the differential diagnosis between an acute follicular tonsillitis, where a large pseudo-membrane has formed on the tonsil, and diphtheria, in the early stages, is extremely difficult, and I would blame no man, however great his experience in throat diseases, if he insisted upon time for his diagnosis. In the meantime, however, every precaution must be taken to prevent a possible spread of the disease.

Let me mention a few of the practical points which I carry in my own mind when brought face to face with such cases. In the vast majority of cases they will enable you to make a correct differential diagnosis.

1. Remember that the membrane of diphtheria does not remain confined to the tonsil, but that it spreads to the uvula, soft palate, and perhaps to the post-pharyngeal wall; in other words, it may leave the tonsil. The pseudo-membrane of follicular tonsillitis never does this.

2. The membrane of diphtheria is so closely adherent to the underlying parts, and you cannot lift it up from the mucous membrane without rupturing the capillary vessels, causing a slight bleeding. The pseudo-membrane of follicular tonsillitis is easily raised from the underlying mucous membrane with a probe; it leaves no abraded surface beneath it, and very often you can draw out with the pseudo-membrane the contents of the follicle, the mouth of which it covers.

3. The diphtheritic membrane is always thick. In follicular tonsillitis the membrane is thin and delicate.

4. The membrane of diphtheria is always of a dirty, yellowish color; the pseudo-membrane of follicular tonsillitis is pure white, or of a pearl-gray; it is clean and bright. The membrane of diphtheria after twenty-four or forty-eight hours becomes necrotic, and takes on a dirty, blackish-gray color—in short, it looks what it is, a necrotic, dead, or dying membrane. The pseudo-membrane of follicular tonsillitis on the other hand, always remains whitish, pearl-white or gray, and never becomes blackish or necrotic.

5. The tonsillar portion underlying the diphtheritic membrane is of a deep red or bluish-red color; the underlying tissues in a case of foilicular tonsillitis is bright red, never of a very dark, angry color.

These points, I am sure, will assist you, as they have often assisted me in making the differential diagnosis between diphtheria and the pseudo-membrane of acute follicular tonsillitis. Of course, we can go further, and with the microscope determine the presence or absence of the Lœffler bacillus, but I have given you the practical, bedside tests which will usually enable you to answer definitely and quickly regarding the true nature of the membrane.

Now, let me say a word about the contagiousness of follicular tonsillitis. Here, I must deal largely with the individual belief. I believe to-day, as a result of my own experience, that follicular tonsillitis is mildly contagious; that it is not safe to put others in the way of direct contagion; and my advice to you is that it is best to isolate the patient, and particularly to

keep children from being around those suffering from this disease. You should also banish from the sick room adults having hypertrophied tonsils, or suffering from any condition which predisposes to such a contagion.

To simplify the treatment for you, I have had the principal points printed on these sheets of paper, and will distribute them among you. I shall run over them briefly.

First, then in the treatment of peritonsillar abscess, in the interval of the attacks, extirpate the tonsils, and get rid of this predisposing cause. In the treatment of the acute attack, I would say that an attempt to abort an attack is occasionally successful, but it will never do it after the first twenty-four hours; therefore, if this period be gone by, immediately administer anti-rheumatic remedies, such as sodium salicylate, salol, oil of wintergreen, and iodide of potassium, and with the first four doses, give one drop of Fleming's tincture of aconite. As a rule no more than four doses of this powerful drug should be administered. If sodium salicylate be prescribed, give about ten grains, every hour. Another useful measure is to allow the patient to frequently apply bicarbonate of soda to the tonsil with the moistened finger, for it gives great relief to the patient, although I cannot say why it does it. I constantly see tonsils which have been cut and maltreated in various ways; I have told you that the abscess is not in the tonsil, and therefore, it is folly to incise the tonsil. Blood-letting by *puncturing* the tonsil will relieve the tension and pain, but I tell you, never scarify. As soon as the existence of pus is established by digital palpitation, open the abscess by a free incision. The general local treatment consists in gargling the throat with water as hot as can be borne, the use of alkaline and disinfectant sprays to wash away the accumulated tenacious mucus; inhalations of steam, or the application of hot flaxseed poultices, frequently renewed, beneath the angle of the jaw. An application of a five or ten per cent. solution of cocaine will allay the pain. The abscess usually forms by the third day, unless it is in dense tissues.

Now, the treatment of acute follicular tonsillitis is simplicity itself, notwithstanding the great variety of drugs and methods recommended in our various medical works. Every case of follicular tonsillitis can be successfully and quickly treated by the following method:

For the stage of fever and lassitude, there is perhaps nothing better than antipyrine. Later on, nothing is better than quinine and strychnine for the physical prostration. Locally, you should administer every hour a half teaspoonful of the following, which should be slowly swallowed, in order that it may diffuse itself about the fauces:

℞ Tinct. Ferri Chloridi..... dr. ij.
Glycerini ..... oz. ij.

You may also apply the tincture of the chloride of iron at regular intervals during the day directly to the croupous deposits on the tonsils, using a kalsominer's brush, one inch wide, which is very much better than the ordinary throat brush. An antiseptic and cleansing gargle is also grateful to the patient. A mixture of listerine and water may be used for this purpose.

In conclusion, then, remember to use the knife whenever necessary, avoid polypharmacy, assist Nature to do her work, and follow the few simple rules which I have given you.

---

### Operating Accident.

A sad and unusual accident is reported to have occurred recently in the operating theatre of one of the London hospitals. One of the surgeons was engaged in sewing up the wound after a laparotomy, and, while in the course of doing so, he seems to have given a flourish to the needle in his hand, which penetrated one of the eyes of his assistant. The latter continued for some moments to attend to his duties, but was afterward compelled, owing to the pain in his eye, to leave the side of the operating table and sit down on one of the benches in the theatre. As soon as the operation had been completed, the surgeon examined the injured eye of his assistant, and found the lens was lying outside the organ, the sclerotic extensively torn, and the vitreous protruding.—*N. Y. Med. Record.*

A lady in distress wrote the following urgent note to her physician: "Dear Dr., please call at once, and bring your urethra with you." He took a catheter.

# COMMUNICATIONS.

## CHOLERA.*

ERNEST HART, London.

*My Professional Brethren*—I have not ventured to bring before you any new theme, or one which would in any way depend upon the eloquence or the special capability of the speaker. I have felt that on an occasion such as this, when you have honored me by asking for an address at the general meeting of this great association, I might most usefully occupy your attention by dealing with the subject which, from its own intrinsic importance and from the influence which it is likely to have, which it can hardly fail to have ultimately on the welfare of the population and the nation, should at least intrinsically demand your attention, whether you give entire assent or not to the proposition I shall have the honor to lay before you.

In dealing with the subject of CHOLERA I am dealing with one which has been perhaps more written about, more discussed, and more talked about than any other in our time. It is the subject of almost universal conversation. Since I have been here, questions have been put to me not only daily, but almost hourly. One is, "What do you think of our country?" as to which you may readily imagine I have been giving answers which I am certain have been very satisfactory. Second, "What do you think of the cholera?" "Is the cholera coming?" Then I will venture to mention briefly what I wish to be able to present to you to-day by an incontrovertible amount of evidence. That is, cholera is no longer a thing to be dreaded; it is no longer a thing to be wondered at; it is no longer beyond control. Although it is only a few years since we in Europe and you in America made the acquaintance of cholera, and when we first came in contact with it, it was the most striking and awful pestilence known to our profession. However, the study and application of a single practitioner—an obscure practitioner, but one of the greatest of the world's heroes—the studies of one man carefully followed out have robbed cholera of all its mystery; have pointed out its causes, and have put before us methods of extinction so certain and so easy that it will be a reproach to every nation, and especially a reproach to those great nations so endowed by nature, if in our own time cholera does not become as thoroughly extinct—as nearly extinct, as much a matter of the past—as typhus or the oriental plague, which have been conquered by medical skill and medical advice.

Every theory, every advance in knowledge, goes through certain very well known stages; as a rule, at the beginning it is denied. That is wholesome and necessary for the proof of its accuracy. The skeptic attitude is the necessary attitude. Presently it is ridiculed, and then comes the stage where its leading facts are accepted. Presently they are accepted, and finally they become so contrite everybody says "O yes, we have always known them."

A distinguished gentleman I have seen here to-day reminded me, in our early text books, the knowledge of cholera was summarized in about these words, "Cholera—Diagnosis, easy; etiology, uncertain; causation, unknown; treatment, useless." Well, now we have modified all that. If I had to take those headings to-day, I think you would agree with me in saying this: Diagnosis, difficult, very difficult—I will show you presently how difficult it is; thus, it is not at all desirable, for the commercial interests of the community, that cholera should be too quickly identified, and where it appears in its first early stages it is spoken of in the most endearing terms. When cholera first comes it is reported as cholerine—an attractive word. Presently, like the pleasant little French songs, it becomes, cholerine-cholera, cholera-cholerine. But, there is nothing more difficult, as our recent science has shown, than the diagnosis of cholerine from cholera, and there is nothing a microscopical examina-

* Address to the Members of the American Medical Association, Thursday, June 8, 1893.

tion will show, whether the early or late cases are cholera or cholerine. The diagnosis is no longer easy. We have yet a great deal to learn about the stages which characterize simple cholerine and Asiatic cholera. Another thing, cholera does not stop, as we suppose. You notice the importance of this in connection with the enormous expenditures and the disgraceful efforts to keep it out—a disease which we have invited, and, having invited by our negligence, try to keep out with quarantine. They are obliged, in virtue of their dirt, to fight a disease invited by dirt. It was at one time supposed a man with cholera must go through certain stages and quarantine was sufficient, but you now know the man may walk about with the cholera and may contaminate an entire water-supply. He may, as at one time, cause 16,000 cases of cholera with 6,000 deaths. Cholera, then, is not easily diagnosed. It is only capable of diagnosis by bacillar examination.

Further than that, you know now very well a man may walk out of a cholera hospital cured, so-called, but with a slight diarrhœa. He may infect a river and may slay a community, for his discharges are often laden with germs. In three cases examined for me, the dejections were found to be loaded with bacilli. You see, then, diagnosis is not certain. We can always know when cholera is about, and should take extra care of all these cases of cholerine and premonitory diarhœa. Now, as to the pathology. The pathology I will not stop with to-day. The pathology has now been immensely cleared up, and the pathology of cholera is now no longer mysterious. We know how to deal with it as we do our other bacteriological diseases. Treatment, useless; we know no more of the treatment of cholera now than we knew of the treatment of cholera thirty years ago. And, that is no reproach to us, because for poisons you may find antidotes or partial antidotes, but an infective disease must run its course.

We know now there is such a thing as an evolution of disease. Cholera is one of those diseases which the public like to think of as a disease which comes by providence and goes by drugs. That is exactly the opposite of the facts. Cholera comes by man; it is a man-created disease, and cholera cannot be cured by drugs. Of course, there are drugs which alleviate and diminish the symptoms. Possibly there are drugs which diminish the number of deaths. But, as at the last Hamburg epidemic, in the early stage and in the later stages of epidemics, when patients are going to get well, everything will cure, and that is the time to try specifics. But, in the essential periods, when the epidemic is at the height, no drugs will modify the mortality.

Now then, as to the causation. We are entitled to say in some parts of Europe cholera will never appear again, and with certain precautions here cholera never can appear again. Now, let me take you briefly—I have here an immense mass of figures, but let me take you briefly over the history and analysis of the great epidemics of cholera since 1853, in order to prove from that precisely the point I am endeavoring to bring to your notice. You know, our first outbreak of cholera in Europe was in 1832. I was just looking here—I expect some here will remember 1832. Well, the Annual Register said the cholera left medical men with most opposite views. We know, first of all, it is epidemic and not endemic. We know it always comes from one place. I am ashamed—I am grieved, more than ashamed—to have to name that source of danger of pestilence to Europe and the world. That is India. It is within the Imperial British domains of India cholera is always found. In the earlier outbreaks from India, cholera usually came across the great seas, across the Caucas, and then by caravans and emigrants reached other towns, and finally that ill-fated city, Hamburg. And then, through Hamburg to Europe in general. The other route was by the Mecca pilgrims, the India pilgrims who carried cholera with them to Mecca, and there, by a process I will show you, diffused it throughout the whole of that country, and then brought it on to Alexandria. From Alexandria it took ship and came to Havre or came to England. That is the course it has pursued now on 25 different occasions. And, I notice this: When people travel on foot, on horseback, by caravans, cholera travels correspondingly slow with them. It took three years to come from Odessa to Europe. And, as steamships and railways have increased, its speed has increased. Cholera, then, travels along the lines of human in-

tercourse and precisely with the rapidity of human intercourse. It makes no backward course. It has its back currents as people rest in a place; it has recurrence as the infection lies dormant. The next point is, that cholera, when we come to examine the facts, is a disease which is always carried by dirty people to dirty places and diffused by dirty water.

Now, let us take the places to which it was carried and see what is the demonstration I can offer you that it was carried by dirty water. Well, we will take, first of all, as an example, London. When cholera first came to London everything was mystery. It was in 1851. We did not know how it came. We thought it was blown by the winds, carried by pandemic waves, and we heard of cholera mists, telluric and meteoric influences and all that jargon. Then came one or two more instances. There was a celebrated pump on Broad Street; it was celebrated and the water most beautiful and sparkling. But water sparkles from human nitrates! Well, the Broad Street pump was a celebrated pump and people were sending from all over London to drink the water. It was suggested that it was precisely the people who were supplied with that water who were the ones that died. A clergyman came up and drank the water. It was very noticeable that he drank brandy with the water, for it was thought brandy corrected the influence of the water. We, of course, know it does not. The whiskey hurts you and does not correct the water.

This gentleman drank brandy in his water and ate a mutton chop, and spoke of his brethren who had died, and then he went home and died. It was afterward found this water became sparkling because of matter from the sewers from the neighboring hospital. This demonstration was carried on, and it was found the amount of cholera in all these subsequent epidemics in London were in precise relation to the water supplied with the animal matter. Of course, animal matter is not pleasant to drink, but some old ladies will not change their drinking water, saying that their fathers and grandfathers have drank it and they refuse to change. Of course, it will not kill until poison gets into it.

In London there are the water companies. During the first epidemic the Lambreth company was the purer. About 137 per 10,000 of the population supplied with that water died with cholera, and only about 67 per 10,000 of those supplied by the other company. The experiment was so large and complete there could be no mistake about it. Houses side by side were supplied by companies furnishing water of various degrees of purity By the time the second epidemic appeared, the second company went a great deal higher up for the water supply, and the water was much purer. The proportion of deaths then was just inverted. It now had 30 per cent. less deaths than the company formerly more innoculous. A very ghastly experiment. There is nothing so sensational in the world. If you, who discuss sanitation, would take trouble to put it in a dramatic form, there is nothing which could so seize the public mind. Now, comes the next fact. In 1866—I was then 23 years of age—cholera broke out in East London. I had no skilled, expert hand, but was firmly convinced from study that its cause must be the water and nothing but water. I got, then, a very well-known gentleman to go down and look at the companies' works, and he came back and said, "There is nothing there. The engineer says the water is the ordinary water supplied in the ordinary way and there has been no change." The same result followed an investigation on the second day, but on the third day I found "Pump out of repair" on the books. Well, to make a long story short, I found one huge pump had been out of order and all the water was pumped directly into the district, that was affected with cholera, without passing through the filter bed. They were supplied with this water two days before the cholera broke out. Well, that was a very striking fact. Then we found it was only people of that district who were suffering with cholera. London escaped, for the district supplied by each company is limited by Act of Parliament, but in five weeks 16,000 people were taken with cholera and 6,000 died.

We will now trace how the cholera got into the water. A ship had come by the well-known route from Alexandria with *only* six or eight cases of cholera on board. The vessel was put in quarantine, the patients put in the hospital, and we had almost forgotten it; but when this occurred we traced these cases and found one had gone to a small town. And there only

16,000 people were killed, including the man, the doctor, the nurse, and 13 people of the village. But then came this other fellow, who was discharged as convalescent and had gone to a cottage on the river, the sewers of which connected with the river. He was taken with relapsing cholera. (If you poison rabbits with cholera bacilli, they will get well; but shortly they have relapsing cholera, when the intestines will be found full of cholera bacilli.) Well the man infected the river just at the very moment the water was taken from this point, in consequence of the breaking down of the pump, and distributed over the town. Thus one unhappy man and one unhappy engineer combined to kill all these people, and all got off Scott free. If any man sells me poison, as many a man does by accident, as an unhappy chemist sells morphia for ice cream, or a baker sells flour mixed accidentally with arsenic, even for his accident you have legal recourse against him; but against the distributing of poison by your water companies you have no recourse. Your municipalities are entitled to distribute cholera at intervals, typhoid fever daily and constantly, in all your great cities, and to poison their unhappy clients and yet go Scot free. They suffer no damage, and you have no remedy against them.

Well now I can show you that is true always with cholera. Since 1866, everybody has been so far convinced of the accuracy of this statement that our main experiments have been on water supply. In England we have spent thirty-five hundred million dollars on water supply, one hundred million dollars within the last year on water supply. I am satisfied we can never have an attack of epidemic cholera in England again. Our water supply is not perfect, and we may have limited outbreaks of cholera, but our water supply now places us in much better shape. We have no fear, and can have no fear of cholera in Great Britain.

The great seats of cholera epidemics have been Spain and Italy. And everybody knows, of course, of Hamburg. In Hamburg they knew they were drinking the filthy and impure Elbe water. But Hamburg is a free municipality—sufficiently under control of the citizens to leave them free to do a good deal of evil and not to do a great deal of good. The greatest mortality rate in Hamburg was down near the river, while further away from the river the mortality rate was much less. Hamburg is as absolute a demonstration of the water-born theory of cholera as the world has ever seen. Also the recent outbreak in the dead of winter near Berlin, where cholera broke out in a lunatic asylum, was a mystery. But it was found a single person had come on from Berlin. In Hamburg, by the way, they have a most beautiful system of irrigation. Charming! And the engineers have so arranged matters that the sewerage all passes out the same way into the river. Just below the outlet of the sewerage is the intake of the water supply. And to make things worse, this being in the dead of winter, everything was frozen, and the matter was taken up by the water supply very nearly pure. So, three or four days after the gentleman came to the hospital from Berlin, they had a tremendous outbreak of cholera. That is also the history of all Paris outbreaks. In Paris, during the warm season, a notice is put up stating the water now is mixed and you are only to drink such and such water. But a great many people cannot afford to drink from that supply, and they always have outbreaks of typhoid and cholera in Paris caused by the impure water supply, and it is stopped as soon as the water supply is changed.

And I may say, if it is supplied with pure water, they will never have another attack of cholera in Paris. Marseilles and Tulon are in the same condition. In Marseilles impure water is taken in, and they pass it out again, running great quantities over the streets to clean them. But, cleaning the streets will not stop cholera if you are drinking impure water. After heavy rains, cholera is usually diminished; but, after heavy rains in Marseilles, it was increased because the unhappy people were drinking the water from the rivulets. That was the cause of the cholera in 1866. When that epidemic reached us, I received a telegram, stating my water-born theory of cholera was at fault. Well, the water theory cannot be at fault. "Trace your water-supply up to the top," I told him, and he soon answered, "Cause found." They had traced it up to the top, and found the cause up the mountain. Cholera was prevalent along the frontier, and they

had the whole frontier lined with police and soldiery. These camped at the top of the water supply. That supply was cut off, and the city deprived of water from that source, and cholera ceased within a week. That was a very striking case. Another striking case, perhaps more striking, was in Naples. I saw a little paragraph, stating, we are all very much afraid of cholera and we are taking every precaution at hand. A few cases have broken out. We are pouring large quantities of carbolic acid in the cesspools, and, odd to say, and disagreeable enough, our drinking water all tastes of carbolic acid. What happened was, cholera came, and there were 70,000 deaths—the most calamatous and vast catastrophy of modern times. The doctors were attacked and assassinated. They have since taken better precautions than religious processions or attacking the doctors. They have obtained pure water from beautiful aqueducts. Naples is immune from cholera. By a coincidence, little outbreaks occurred, and at the precise period when the aqueduct was being repaired, and at the moment it was repaired the cholera ceased. Naples, from being the most susceptible to cholera, is now one of the most immune, as any great city may become when you compel your municipalities to do their duty, to supply pure water, pure air and pure soil.

I shall not now detain you further than to point out this, that the latest results of microscopical examination and bacteriological research fully confirm this vast mass of evidence, collected from every city, every country, every epidemic of the last half century. Whereas, clinically and statistically, we can say on a basis of facts and figures, there never has been a country experience an outbreak of cholera, where the cause cannot be traced to the distribution of infected water. That is a matter of clinical observation. So, we may say scientifically now, we thoroughly understand why that is. We know the characteristic cause of cholera is a bacterium, which has this simple property: It is not in itself, and while fresh, very poisonous; that it is not an anærobe but is an ærobe, and its favorite method of development and propogation is in soil and water. The cholera bacillus is not easily communicated in the fresh stage, and it is not easy to infect guinea pigs or other animals with it, but if you cultivate it or let it cultivate itself in water, it becomes very effective, and becomes more virulent as it is multiplied in soil and in water. It is interesting, by the way, to notice it is difficult to infect healthy guinea pigs; but if you dose them with brandy or whisky and make them unhealthy, or if you give them opium, they are easily infected. Acid drinks, sulphuric acid and citric acid, have been shown to be very useful as preventatives. So, all these experiments confirm the broad facts which we have been able to learn from the examinations, and the final result is, if we can exert our influence upon State boards of health, to bring home a sense of responsibility to the executive officers of State, we shall be able to boast as a profession that we have in our generation pointed to the extinction of two great plagues of mankind. We have shown how three plagues can be exterminated, and we should hear no more from typhoid fever or typhus fever. Deaths from these diseases are just as much violent deaths as deaths from arsenical poisoning. They should be the subject for inquest, and it is for us to extend, not only to the rich who can buy mineral waters of all sorts, but to the poor who cannot always obtain sterilized water or boiled water, and for whom we ought not indeed to poison the water and require them to purify it. We should always be supplied with pure drinking water.

### Put a Strong Stick in it.

The drug-store proprietor had employed a new boy for $3 a week. "I'll have a little stick in mine," said the man at the soda water counter. "A little what?" asked the boy. "A little stick," repeated the man with embarrassment. "In your soda-water?" "Yes, of course." The boy prepared the mixture. The man took a swallow, gasped, gurgled, and coughed. and, when he caught his breath, said," "What in thunder did you put in that soda-water?" "Well, sir," replied the boy, "I wouldn't have done it if you hadn't insisted; but as long as you wanted it I gave you the best brand of mucilage there is in the shop."—*Washington Star.*

# OVARIOTOMY ON PATIENTS OVER SEVENTY, BY AMERICAN OPERATORS.

MARY SHERWOOD, M. D., Baltimore, Md.

In a report of 5 cases of laparotomy performed on patients over seventy years old, published in the *Lancet*, January 21, 1893, J. Rutherford Morison states: "Long lists of successful ovariotomies can no longer serve any good purpose, for it has been proved that the mortality of ovariotomy should not exceed 5 per cent. My excuse for publishing the following cases is the advanced age of the patients. Sir G. M. Humphrey long since pointed out that in old people repair and recovery are likely enough to follow major operations. This is true of abdominal sections —a fact not sufficiently recognized." That this statement is emphasized by facts is shown most conclusively by the statistics in the list of 100 cases of ovariotomy performed on patients over seventy years of age, which I have recently assisted Dr. Howard A. Kelly in collecting. While a complete tabulated statement of these cases, with an analysis of the same and inferences drawn therefrom, is reserved for publication in the *Johns Hopkins Hospital Reports*, at the suggestion of Dr. Kelly I have taken the cases reported by American operators as the basis of the present paper.

That special attention might be called to the cases of American surgeons seems appropriate as this list includes: 1. The earliest case found in the literature on the subject; 2. The oldest case on which ovariotomy has been successfully performed; 3. The greatest number of cases reported by any single operator.

The first ovariotomy on record as having been performed on a woman over seventy years old, was the case of E. P. and Wm. C. Bennett, of Danbury, Conn., who on the 17th of August, 1861, operated on a patient aged seventy-five years. An incision two inches long was made and seven or eight sacs emptied with a trocar. Silver sutures were used in closing the abdomen. The patient "recovered without any mishap."

To Dr. John Homans, of Boston, belongs the honor of having operated on the oldest case on record. In the *Boston Medical and Surgical Journal*, May, 1888, he reports a case of ovariotomy in a patient aged eighty-two years and four months. He removed a multilocular cyst of the left ovary, weighing fifteen pounds, and in December, 1892—four years after operation—reports the patient as alive and well. In addition to having operated on the oldest case recorded, Dr. Homans reports 12 cases of ovariotomy in women over seventy years of age, the greatest number accredited to any single operator.

The table included in this paper contains 38 cases from the original list. Of this number, 33 recovered from the operation, 5 died, giving a mortality of 13.1 per cent. The mortality as based on the complete list of 100 cases is less than this (12 per cent.). The results of the operation are, therefore, very encouraging when one considers that, according to Bland Sutton, in experienced hands the mortality of ordinary ovariotomy varies from 5 to 10 per cent. This rate of mortality becomes increasingly suggestive when it is noted that in the series only 9 cases are reported as simple and uncomplicated. In 23 cases adhesions were more or less numerous, necessitating in 2 cases the removal of the uterus. In this connection the table seems to establish the fact that age in itself need not be considered an additional factor in the prognosis of ovariotomy. In the case of Boldt, the patient was seventy-four years old, cachectic, and much emaciated, with moderate ascites. The entire tumor was firmly adherent, many adhesions so dense as to require severing with scissors or knife; there were also adhesions with intestines. The retro-peritoneal glands were enucleated. The tumor proved to be a multilocular cyst of the left ovary of which the lower and posterior portions as well as the enucleated glands were carcinomatous. This operation was performed in March, 1887, and Dr. Boldt reports the patient as still living—nearly six years after operation. In one of Homans' cases the tumor was so adherent to the uterus that the body of the uterus had to be removed also. The case was that of a woman,

aged seventy-two, from whom Dr. Homans had removed the right ovary five years previously, who had remarried after recovery from this operation, and from whom he now (1877) removed a multilocular cyst of the left ovary together with the uterus. In December, 1892, he reports the patient as living and well. In June, 1890, Dr. H. Marion Sims operated on a patient aged seventy years, removing a multilocular cyst of right ovary, weighing eight pounds, adhesions being so extensive that he was obliged to remove the uterus also, and the patient recovered and is reported as still living in January, 1890.

As the nature of the tumor is an important factor in estimating the results of the operation, an examination of the table shows that the most frequently occurring tumor is the multilocular cyst. Unfortunately, in a majority of the cases there is no histological report of the nature of the tumor extirpated. In one instance—a case of Dr. Kelly's—a careful microscopical examination showed areas of adeno-carcinoma in the cyst wall; another cyst was cancerous at base with involvement of the retro-peritoneal glands, while two of the multilocular cysts are reported as papillomatous; sarcoma, dermoid, solid tumor are noted once respectively, and in seven instances the cyst is unilocular. The absence of results of microscopical examination in some cases makes it impossible to reach any accurate decision as to the percentage of malignancy, although in seven instances the tumor is stated to be non-malignant.

With regard to the ovary affected, we have the statement in 27 cases, in 10 of which the tumor was of the right ovary, while in 17 the left was affected. It is interesting to note that in our list of 100 cases, 72 of which report on this point, the right ovary is involved in 38, the left in 32 cases (in 2 cases both ovaries being affected). No evidence is, therefore, afforded that either ovary is the more frequent seat of disease.

The time of first appearance of symptoms in the majority of our cases shows that the tumors were for the most part rapidly growing, in 6 instances the observation being made less than one year before operation, while in 19 the time was between one and two years. The remaining 6 cases which report on this point give a time varying from three to ten years.

The subsequent history of these cases is a point of great interest; and here, too, the facts of our table give definite information in many instances. As was stated above, 5 patients died within ten days after operation. Of 8 cases reported as dying subsequently, 4 lived less than a year, while 4 others lived from 5 to 10 years after operation. The cause of death in these 8 cases is variously given—pneumonia, heart disease, old age, etc.

Eighteen patients recovered from the operation and are reported as living at present—*i.e.*, in January, 1893, when the facts for the table were collected. In two cases only was this report given less than a year after operation. Nine patients were alive and well one to three years after, and seven have survived operation and are still living from three to ten years after. Evidently we can draw no conclusion from the after-history of the patients against the advisability of operating on the aged, in the face of the fact that 16 of these 38 patients lived from two to ten years after the operation was performed, 12 of this number being alive at present.

The facts shown by our statistics summarized briefly are:

First, that the operation of ovariotomy in the aged presents no essential differences from this operation in cases of younger years.

Second, that the percentage of recovery from this operation in patients over 70, as shown by the results of American surgeons, is 86.8 per cent., the mortality 13.1 per cent.

Third, that the indications and contra-indications for ovariotomy in the aged are essentially the same as for this operation in general.

### The Surgeon's Enemies.

The surgeon's enemies are almost always sporeless bacilli, and though some of these show great resistance to the action of antiseptics, such as the staphylococcus pyogenes aureus, the common cause of suppuration, it has nevertheless been shown that carbolic acid destroys these organisms more rapidly than corrosive sublimate.—Lister.

# SOCIETY REPORTS.

## AMERICAN MEDICAL ASSOCIATION.

*Forty-fourth Annual Meeting, held in Milwaukee, Wisconsin, June 6, 7, 8, and 9th, 1893.*

### SECTION ON SURGERY AND ANATOMY.

Continued Report.

*Chairman*, Dr. James T. Jelks, of Hot Springs, Ark.

*Secretary*, Dr. Liston H. Montgomery, of Chicago.

The Section was called to order by the Chairman, who delivered an address on

THE ANTIQUITY OF SYPHILIS, AND MOSES AS A HEALTH OFFICER.

He dwelt upon the plague that afflicted Pharaoh and his household to strengthen the relationship of syphilis as it existed at that time and as it exists to-day.

Dr. A. J. Ochsner, of Chicago, contributed a paper entitled

A REPORT OF THREE CASES OF ACUTE INTESTINAL OBSTRUCTION TREATED BY LAPAROTOMY:

(1) Intussusception; (2) Volvulus; (3) Meckel's diverticulum.

The first case was that of a boy, aged three years, who, a week before coming under observation, fell and immediately felt slight pain in the cecal region, but of brief duration. Occasional pains were experienced during the next few days. At the end of a week severe spasmodic pains were felt in the abdomen, with nausea, vomiting, and a constant desire, with ineffectual efforts, to evacuate the bowels. Intussusception was diagnosticated and the diagnosis confirmed by celiotomy. The vermiform appendix seemed to have been thrown around the ileum, the constriction thus produced leading to the intussusception. The appendix was removed after reduction had been effected. On the fifth day the bowels were moved by a glycerine and water enema. The stitches were removed on the ninth day and the wound supported with adhesive strips. The pulse and temperature were but slightly affected, and the recovery was rapid and complete.

The second case occurred in a man 32 years of age, who fell into a ditch two or three feet deep, experiencing a slight pain in the left inguinal region. Two days later the abdomen became swollen and painful, and there were nausea and constipation. A globular enlargement could be seen in the lower part of the abdomen. Purgatives had been administered for two days without effect, except to increase the pain. Volvulus was suspected, and an operation for its relief undertaken. On opening the abdomen the suspicion was confirmed. The sigmoid flexure was found so distended that replacement within the peritoneal cavity was impossible. A rectal tube was passed, liberating a large amount of gas, after which the bowel could easily be replaced. After the fifth day the bowels were moved daily by enemata. Complete recovery followed without incident, the patient being dismissed thirty days after operation.

The third case occurred in a man aged 81 years, who, while in apparent health, suddenly developed the symptoms of acute shock. There was a sudden severe pain to the right of the umbilicus, which was thought to be due to the presence of gallstones. An anodyne gave relief for two days; then the abdomen became uniformly distended. There were nausea and vomiting, first of the stomach contents, and later of stercoraceous matter. There was no point of special tenderness. An operation was undertaken, and a loop of small intestine was found to have slipped through Meckel's diverticulum. The adhesions were so firm that it was necessary to apply double ligatures and cut between them, so that the condition must have been one of long standing. After the operation, uncontrollable vomiting continued and death occurred thirteen hours later, without reaction having taken place. Regret was

expressed that the stomach was not washed out, as this might have relieved the vomiting. Earlier diagnosis and a younger age would both greatly have increased the chance of recovery.

UNNECESSARY RESTRICTIONS TO SURGERY.

Dr. John B. Roberts, of Philadelphia, contributed a paper on this subject, in which he entered a plea for the treatment of every surgical case on its merits rather than by rule. The opinion was expressed that many patients are detained in bed unnecessarily long on account of fractures of the bones of the legs, and that patients with fractures of the forearm are often likewise burdened with cumbersome dressings long after the usefulness of these had ceased to exist. Sprains and chronic joint-affections often demand massage and passive motion, rather than continued rest. It was held that the habit of restricting the diet of patients for days after an operation is unnecessary, as well as a large number of other customs that have been taught and practiced for so many years that almost no one stops to consider whether they are rational or not.

Dr. John E. Link, of Terre Haute, Ind., reported cases affording evidence of the surgical immunity of the peritoneal viscera. He gave the results of many operations performed in the most careless manner on dogs, and always with recovery of the animal. The object was to show that, when skilled surgical aid cannot be obtained, the family physician should proceed to operate in cases of abdominal injuries or other serious acute conditions, inasmuch as the peritoneum is much more tolerant of invasion than has been generally supposed, and the danger of delay in operating far out-weighs that to be feared from opening the abdomen. Dr. Link demonstrated his method of operating on dogs, and showed several specimens taken from animals previously operated upon.

---

WEDNESDAY, JUNE 7TH—MORNING SESSION.

Dr. C. Fenger, of Chicago, read a paper entitled

OPERATIONS FOR STRICTURE OF THE URETER IN HYDRONEPHROSIS AND PYONEPHROSIS.

He said that in hydronephrosis or pyonephrosis there must be an obstruction somewhere. In many cases of intermittent discharge, the difficulty is due to oblique insertion of the ureter into the pelvis, and the consequent formation of a valve at the point of junction. The fluid is prevented from passing until the distention and pressure are sufficiently great to overcome obstruction, and the accumulation escapes. Dr. Fenger has operated on such a case by splitting the valve and stiching its margins apart after opening the pelvis. Strictures of the ureter also cause hydronephrosis or pyonephrosis. They may result from ureteritis or from indirect traumatism. A case was reported in which pyonephrosis developed two years after a fall. An operation was performed, the stricture divided longitudinally, and stiches passed in the same direction as the line of the incision, thus converting the longitudinal into a transverse wound. The appearance of blood in the urine for a few days demonstrated the patulousness of the ureter. Recovery was complete. The best incision for this operation is the lumbar one, from the twelfth rib to the crest of the ilium, and then extended to the middle of Poupart's ligament. This gives ready access to the upper two-thirds of the ureter. The lower third can be reached by sacral resection. The value of relieving obstruction to the ureter is shown by the fact that after nephrotomy a fistula remains in 45 per cent. of the cases; while nephrectomy is to be avoided if possible, as the condition of the opposite kidney is generally not known, and the radical operation may result in speedy death from uremia if the second kidney is also diseased.

WHAT OPERATIONS MAY WE PERFORM ON THE GALL-BLADDER?

Dr. J. B. Murphy, of Chicago, followed with a paper on this subject, in which he said that the function of the gall-bladder is to regulate the pressure in the bile ducts, as the air chamber does in the steam pump. In support of this view, reference was made to the fact that the bile is always much more concentrated in the gall-bladder than any of the ducts, and also that in a very large number of operations upon the living subjects, the cadaver, and upon animals, the gall-bladder was never found empty in health. The pathological conditions of the gall-bladder calling for operative interference are chiefly cholelithiasis, cholecystitis,

carcinoma of the head, of the pancreas, neoplasms involving the ducts, carcinoma of the gall-bladder and trauma. The operations, naturally, all necessitate celiotomy. Of 25 cases of simple puncture collected, one-fourth terminated fatally. This is to be explained by the fact that the walls of the gall-bladder are so dense and so slightly contractile that the puncture opening remains patulous, and thus allows the contents to continue to escape. In 23 cases in which an incision was made and drainage provided for, the mortality was 18 per cent. Dr. Murphy has had made a modification of his anastomosis-button, in which one part is two and a half or three inches in length, and being hollow, allows the bile to escape entirely externally to the peritoneal cavity, so that it is impossible for any leak to occur. In 59 cases collected, in which cholecystotomy was performed in two sittings, the death-rate was but ten per cent.—a very favorable showing. The same operation performed at one sitting, as advocated and practiced by Tait, is a much more serious procedure. Of 201 cases operated on by this method, 25 per cent. died, and in many others a sinus persisted. Incision with immediate suture—ideal cholecystotomy—has been practiced a number of times. In 30 cases collected there were 6 deaths—a mortality of 20 per cent. Dr. Murphy advises joining the gall-bladder with the intestine (cholecysto-enterostomy) in all cases in which it is necessary to perform cholecystotomy. This permits of complete closure of the abdominal incision, and digestion is not impaired by the escape of bile externally. Nussbaum was probably the first to employ this procedure, but on account of the great difficulty in effecting the anastomosis, the operation was gradually abandoned. By means of the anastomosis-buttons designed by Dr. Murphy, the operation becomes a simple one that can be quickly performed. Eleven cases have been collected. Seven have been operated on by Dr. Murphy himself; recovery taking place in all. Two other operations mentioned were also successful. The method was demonstrated by an operation on a living dog.

INTESTINAL ANASMTOMOSIS BY AN IMPROVED METHOD WITH TWO PLATES AND WITH TWO KNOTS; EITHER SILK OR CATGUT MAY BE USED.

This was the title of a paper read by Dr. M. E. Connell, of Wauwatosa, Wis. The author exhibited specimens and explained the operation by reference to diagrams. He said end-to-end approximation or lateral apposition may be practiced, the latter being the simpler. The operation is performed as follows: After making the necessary incisions, a suspending loop is inserted in the bowel just beyond the ends of the cuts, and held by an assistant. A suture, three feet long, is made to transfix all of the coats of one margin of the wound, and passed in the opposite direction through all the coats at a corresponding point on the other end of the bowel. This is repeated until the whole length of one side of the wound has been traversed, always leaving a loop of an inch or two.

Then, by turning the bowel over, the other margin of the wound is closed by passing stitches in the same manner; but this time drawing them taut so as to close the wound, This having been completed, the two ends of the first suture are pulled upon, and, after the apposition is accurate and firm, a knot is tied in each end. After the second knot has been tied both ends are cut loose.

Dr. E. W. Andrews, of Chicago, had used Dr. Murphy's buttons in a recent case of strangulated femoral hernia in which it became necessary to resect fifteen inches of gangrenous intestine. He made an end-to-end approximation. The subsequent course of the case was favorable, and there was prompt and satisfactory recovery.

Dr. H. O. Walker, of Detroit, said that one of the strongest points in favor of performing anastomosis by Murphy's method was the short time required to do it.

Dr. Bayard Holmes, of Chicago, read a paper entitled

A CASE OF CHRONIC GLADERS WITH RECOVERY,

in which he said that glanders in man is of two kinds: (1) acute, in which death usually occurs in three or four months, and (2) chronic, in which the patient may recover after three or four years. In the case reported, the patient was a farmer twenty-two years old, who had always enjoyed good health. In December, 1889, one of his horses became stiff, had a dis-

charge from the nose and died in a week. The mate of this horse also became sick, and had numerous pustules over the body. In a short time the patient noticed a sore on one of his fingers. The affection was thought to be a carbuncle. In a short time five foci of the disease appeared in different portions of the body. There was at first sharp, burning pain, like that which follows the sting of an insect, and deep swelling. At three points spontaneous opening took place. When the patient came under observation, it was decided to remove the disease radically by the cautery instead of the knife. The diseased area was scraped thoroughly, the surface brushed with a strong solution of zinc chloride and packed with iodoform gauze dipped in a concentrated solution of potassium iodide. In all, fourteen different lesions appeared, requiring twenty different operations. Adenitis occurred but once. The diagnosis was confirmed by inoculation of animals.

A NEW OPERATION FOR VARICOSE VEINS.

Dr. Ernest Laplace, of Philadelphia, read this paper, in which he said the operation consists in ligating the long saphenous vein at the saphenous opening, and the short saphenous vein between the two heads of the gastrocnemius. The after-treatment consists of rest in bed, elevation of the limb, and careful wrapping in cotton. The patient may be allowed to arise in two or three weeks. Seventeen cases were reported, in six of which the operation was bilateral. All did well, and the ten recently heard from remain free from their trouble. Cocaine anæsthesia was used.

Dr. B. M. Ricketts, of Cincinnati, followed with a paper entitled

SPECIMENS DEMONSTRATING THE OPERATION OF GASTRO-COLOTOMY, END-TO-END ANASTOMOSIS OF GUT, AND THE CONNECTING OF THE GALL-BLADDER WITH THE ALIMENTARY TRACT, AS PERFORMED WITH THE MURPHY BUTTON, AND BY THE MANSELL OPERATION.

The conclusion arrived at from experiments on animals was that the operation of Mansell was one of the best methods so far described. It could be rapidly performed, and met all of the requirements.

Dr. Thomas H. Manley, of New York, read a paper entitled

A FEW NOTES ON TIBIO-TARSAL, TARSAL, MEDIO-TARSAL, TARSO-METATARSAL, PHALANGEAL, TRAUMATIC AND ARTIFICIAL AMPUTATIONS IN THE LOWER EXTREMITIES. SUBSTITUTES FOR PARTS LOST IN THIS SITUATION.

In cases of traumatism of the lower limb the author made a plea for more conservative surgery. He held that not a particle of tissue should be sacrificed that would survive. A secondary operation was to be preferred, if the patient so desired, for the cosmetic effect or the greater usefulness of the member.

Dr. I. N. Quimby, of Jersey City, agreed with the author to save all tissue possible. In 1887, he introduced a modification of Pirogoff's amputation, in which he does not resect the ends of the tibia and fibula, but places the sawn surfaces of the os calcis against the articular surfaces of the tibia and fibula. He regarded this as very important in the case of children, as the epiphysis was thus spared, and the growth of the bone not interfered with.

Dr. Donald Maclean, of Detroit, maintained that the mere removal of the articular cartilege would not interfere with the epiphysis. He considered Syme's operation as the best in this situation and practiced it, especially when the operation was performed for disease.

Dr. Summers, of Wisconsin, desired to endorse the procedure recommended by Dr. Quimby, and declared that a recent traumatic surface united better to a serous surface than to another traumatic surface.

APPENDENDICITIS, WHAT IT IS AND WHAT IT IS NOT, FROM A SURGICAL STANDPOINT.

By Dr. Joseph Hoffman, of Philadelphia. The author said that it was now settled that the appendix was situated in the peritoneal cavity, and, therefore, all inflammations of the process were intra-peritoneal. The anatomical relations of the appendix were such that a considerable degree of mobility was permitted, and the symptoms of appendicitis, therefore, varied in different cases. The presence of pus was always an indication for operation without delay.

Dr. J. B. Murphy, of Chicago, said he would remove the appendix in every case as soon as he had made the diagnosis. He had operated ninety-five times for removal of the appendix with seven deaths, five from general peritonitis, which had been present before the operation, and two from pyemia.

Dr. N. Senn, of Chicago, said we should be cautious not to operate without due consideration, as the operation might present considerable difficulty. Removal of the appendix was to be recommended in recurrent attacks.

Dr. Joseph Ransohoff, of Cincinnati, contributed a paper entitled

THE EXTIRPATION OF ANEURISMS,

and reported two cases treated in this way. One was a case of bronchial aneurism; the other a case of anterior tibial aneurism. In each case an incision was made over the tumor; the vessel traced in both directions; two ligatures applied, both above and below; the artery cut between and the tumor enuncleated. The following propositions were submitted: (1) Extirpation is the ideal operation; (2) in aneurisms of the forearm and leg, no other method should be employed; (3) in aneurisms that suddenly enlarge, and when rupture seems imminent, extirpation should be employed; (4) in recent traumatic aneurisms, the vessels should be ligated above and below, and if a sac has formed, this should be removed; (5) after other methods have failed, extirpation should be employed; (6) arterio-venous aneurisms should be subjected to the same treatment; (7) proximal ligation may be performed when the age of the patient, the location or other causes contra-indicate extirpation.

AN OPERATION FOR ANTERIOR CLEFT PALATE IN INFANTS AND OLDER CHILDREN.

By Dr. John A. Wyeth, New York City. He advises first to drill two holes in the hard palate; pare the mucous membrane from the margins of the cleft, and, with strong scissors or with delicate bone forceps, divide the alveolus on the short side at about its middle, and slide the anterior fragment forward and wire in this position. This closes the anterior part of the cleft. The lip may be operated on at the same time, or subsequently, as seems best.

JUNE 8TH—THIRD DAY.

The first paper read was by Dr. Frederick C. Schaefer, of Chicago, entitled

BRAIN SURGERY,

In which he reported 8 cases. These cases demonstrated the importance of carefully examining every case of injury and of prompt surgical interference in all instances in which a fracture is detected, even if there be no symptoms indicating intra-cranial involvement. In one case, in a man, fifty years of age, in which there was most extensive fracture of the anterior fossa of the skull and of the frontal bone, the patient walked a distance of a mile to his home. There were no symptoms whatever of any cerebral disturbance when the patient was first seen. Operation was advised but refused, and the wound was treated antiseptically.

ARTIFICAL OPENING OF PULMONARY CAVITIES; INSERTION OF RUBBER TUBE AND INJECTION OF CHLORINE GAS.

Dr. E. L. Shurly, of Detriot, read a paper on this subject. The author said that, although pulmonary cavities had been opened artificially occasionally since 1847, the procedure had only recently been recognized as a justifiable one. He recommends the additional injection of diluted chlorine gas into the cavities at intervals of three or four days. The gas is obtained by half filling a Wolff bottle with fresh chlorine water, forcing air through this into the pulmonary cavity.

Dr. J. MacFadden Gaston, of Atlanta, contributed a paper on

THE PRESENT STATUS OF THORACIC SURGERY,

in which he summarized as follows:

1. All penetrating wounds of the thorax may be closed hermetically by suture after allowing the discharge of fluid blood from the opening.

2. Foreign bodies lodged in the bronchi may be removed by incision of the trachea at the lowest available point.

3. Experiments for reaching the bronchi through the chest wall afford little encouragement in undertaking operation upon the human subject.

4. Medication as a preventive and curative agency in pleuritic effusion is worthy of trial before recourse to operation.

5. Aspiration is indicated when there are large serous accumulations, and likewise in pneumothorax, but cannot be relied upon for the relief of purulent collections.

6. Partial resection of ribs is attended with better results in some cases of empyema than the complete removal of the segments of several ribs.

7. The excision of a small portion of one rib, with the introduction of drainage tubes, has been generally attended with good results.

8. Washing out the cavity of the chest is not requisite, except in case of contamination and decomposition of the contents.

9. The operation of thoracotomy for abscess and gangrene of the lung should be accompanied with antiseptic applications and with gauze tamponage.

10. Tumors of the mediastinum admit of interference, but further improvements are requisite.

TUMORS OF THE NECK,

by Dr. William A. Rodman, of Louisville. In this paper the author considered the various cysts of the neck, and of these, those connected with the thyroid gland are quite common. In the treatment of such cysts, the speaker said that Kocher recommended partial excision of the gland. Total excision led to the cachexia strumipriva. In 18 cases of total extirpation observed by Kocher, but two failed to develop the cachexia; while of 28 partial excisions, no untoward after-effects were exhibited in any of the cases. Lymphomata of the neck were by far the most frequently observed. Sarcoma was more common than carcinoma. Unless seen early, cases of sarcoma of the neck did not offer satisfactory conditions for surgical interference. The author recommended the removal of tuberculous glands of the neck, as the infection spreads through the lymphatics and involves other glands.

Dr. Joseph Price, of Philadelphia, read a paper entitled

THE RELATIVE MERIT OF THE PRESENT METHODS OF TREATING PYELO-NEPHROSIS.

When the patient cannot stand a prolonged operation, incision and drainage should be employed. If there remains any secreting structure of the kidney, it is well to perform nephrotomy, as the possibility of a horseshoe kidney should be borne in mind. In this event, removal would result in speedy death from uremia. In the surgery of the kidney, as elsewhere, the simplest procedure that will meet the indications should be employed. Dr. Price related that he had performed incision, irrigation, and drainage in seven cases without a death.

THE SURGERY OF THE URETER,

by Dr. W. Van Hook, of Chicago. He said that the fact that the ureter was sometimes injured during abdominal and pelvic operations led him to devise a means of uniting the divided ends. One end is lighted, a longitudinal incision made above the ligature, and, by means of two threads, the other end is invaginated into the longitudinal incision. The opposed portions are carefully united, and if desired, covered with a flap of peritoneum to make the union more perfect. It is recommended, when it is desired to implant the ureter in the bladder, that the ureter be first stitched in the abdominal wound, and later, the bladder stitched as high as possible in the abdomen; and when adhesions have become firm, the ureter may be implanted in the bladder with considerable hope of entire success. It necessitates three sittings to complete the operation, but the results justify the method. The author advises against implantation of the ureter into the rectum. Other objections were the occurrence of ureteritis and pyelitis.

The speaker presented the following general considerations:

The extra-pelvic portion of the ureter is most readily and safely accessible for exploration and surgical treatment by the retro-peritoneal route; hence all operations upon the ureters above the crossing of the iliac arteries should be performed extra-peritoneally, except in those cases in which the necessity for the ureteral operation arises during celiotomy. The intra-pelvic portion may be reached by incision through the ventral wall, the bladder, the rectum, the vagina in the female, or the perineum in the male. The ureter is not only exceptionally well protected from injury, but by its elasticity and toughness resists violence to a remarkable degree. The histology of the ureters furnishes most favorable conditions for the healing of wounds. Longitudinal wounds of the

ureter at any point heal without difficulty in the absence of septic processes and under the influence of ample drainage. In all injuries, when the urine has been septic before operation, or when the wound is infected during the operation, drainage must be effected posteriorly. The chemical composition and the reaction of the urine should be studied in all injuries of the ureter, the urine being rendered acid if possible and the specific gravity kept low. The pelvis of the ureter is, *cæteris paribus*, the most favorable site for wounds of the ureter, as scar contraction is not likely there to be productive of ill results. In aseptic longitudinal wounds of the ureter occurring in the course of celiotomy, suture may be practiced as recommended by Tuffier, and the peritoneum protected by suture. Transverse wound of the ureter involving less than one-third of the entire circumference of the duct, should be treated by free extra-peritoneal drainage and not by suture. In transverse injuries in the continuity of the ureter involving more than one-third of the circumference of the duct, stricture by subsequent scar contraction should be anticipated by converting the transverse into a longitudinal wound and introducing longitudinal sutures. In complete transverse wounds of the ureter at the pelvis, sutures may be used if the line of union be made as great as possible. In complete transverse injuries of the ureter in continuity, union should not be attempted by sutures. In complete transverse injuries of the ureter in continuity, union with subsequent scar contraction may be obtained by lateral implantation. In complete transverse injuries of the ureter very close to the bladder the duct may be implanted, but with less advantage into the bladder directly.

In transverse injuries of the ureter with loss of substance, the following conclusions were formulated:

1. At the pelvis of the ureter, continuity may be restored by Kuster's method of suture, provided the several ends can be approximated.

2. Rydygier's method of ureteroplasty in such injuries should be tried, if sutures cannot be utilized.

3. The primary operation should at least fix the ends of the tube as nearly together as possible. In both intra-peritoneal and retro-peritoneal operations the urethral ends can be approximated, even after the loss of about an inch of substance.

4. The use of tubes of glass and other materials for the production of channels, to do duty in place of destroyed ureteral substance, is rarely successful, and even if temporarily successful the new duct is almost sure to be choked by scar contraction.

The implantation of the cut ends of a ureter into an issolated knuckle of bowel is objectionable: (*a*) Because the bowel is not aseptic; (*b*) because the operation is dangerous. In injuries of the portion of the ureter within the pelvis, with loss of substance, the ureter should be treated as follows: If possible the continuity of the uterer should be restored by lateral implantation. If this is not possible, the ureter in vaginal operations, particularly in vaginal hysterectomy, should be sutured to the base of the bladder, with a view of future vesical implantation or formation of a vesico-vaginal fistula with kolpokleisis. In injuries to the pelvic ureter during celiotomy, when the continuity cannot be restored, and when vesical or vaginal implantation cannot be effected in the female, or vesical implantation in the male, the proximal extremity of the duct should be fastened to the skin, at the nearest point to the bladder arch. In such cases, as well as in ventral ureteral fistulae due to other causes, the bladder may be distended and sutured to the abdominal peritoneum and muscles as high as possible, and at a second operation the ureter may be implanted extra-peritoneally into the bladder. If the ureter will not reach the bladder, a flap of bladder wall may be cut out extra-peritoneally and reflected upward to meet the ureter and form a tube. It is legitimate under such circumstances to try Rydygier's method.

Implantation of one or both ureters into the rectum is absolutely unjustifiable under all circumstances, because: (*a*), the primary risk is too great; (*b*), there is great liability to stenosis at the point of implantation; (*c*), suppurative uretero-pyelonephritis is almost absolutely certain to occur. Ligation of the ureter to cause atrophy of the kidney is unjustifiable.

ANALYSIS OF ONE HUNDRED AND TWENTY-FIVE CASES OF HERNIA OPERATED ON FOR THE PURPOSE OF RADICAL CURE.

by Dr. Henry O. Marcy, of Boston.

The author said, continued experience and observation had confirmed the opinion formed many years ago, that the army of truss bearing sufferers will constantly grow less and less, as cases of hernia are subjected to proper operative procedures. The mortality of radical operations for hernia in good hands was very small, and the proportion of cures was very creditable.

Dr. Donald Maclean, of Detroit, followed with a paper entitled:

TRAUMATIC ANEURISM OF THE COMMON FEMORAL ARTERY, WITH LIGATURE OF THE EXTERNAL ARTERIES.

He reported two cases, and on account of the position of the aneurism, and the numerous and important branches that the femoral artery gives off, he deviated from the treatment usually followed and ligated the external iliac artery. Both cases recovered.

Dr. D. J. Hayes, of Millwaukee, reported two cases in which he had operated for the establishment and maintenance of a urethra above the symphysis pubis in chronic prostatic obstruction. The speaker paid a compliment to Dr. Hunter McGuire, who first devised the operation for this condition. The procedure was to be recommended on account of its ease of performance and the very satisfactory results.

THREE CASES OF TRAUMATIC RUPTURE OF THE SMALL INTESTINE, WITH EARLY OPERATION.

This was the title of a paper read by Dr. H. C. Dalton, of St. Louis. One case termimated fatally on account of operation being delayed too long. The other cases made satisfactory recoveries. The author urged immediate operation in such cases.

Dr. Howard A. Kelly, of Baltimore, read a paper on

URETERECTOMY.

He exhibited several photographs, showing the incision and various steps of the operation.

Dr. I. N. Quimby, of Jersey City, reported the case of a boy in which, a few hours after receiving a blow upon the head by a stone, convulsions supervened. It was decided to trephine after consultation. A button of bone was removed and the internal table was found much depressed and splintered. The patient made a complete recovery.

---

JUNE 9TH—FOURTH DAY.

Dr. A. Dallas, of New York City, contributed a paper entitled:

A NEW TREATMENT OF HERNIA,

in which he is said he devised a new form of truss, which consisted of a covered steel spring which was adapted to the body over the iliac crests, the anterior arm descending almost vertically and covering the entire inguinal canal. Perfect retention with the least pressure, comfort in wearing, and stability in proper position were the advantages claimed for the truss. The author recommends the employment of hypodermatic injections of morphine and atrophine every 15 minutes until the patient is comfortable, in cases of strangulated hernia, these injections to be made about the hernia. Should operation finally become necessary, it may be performed under morphine narcosis. A modification of MacEwen's operation was advised for the radical cure.

Dr. Ernest T. Tappy, of Detroit, read a paper entitled,

A CASE OF SUCCESSFUL END-TO-END SUTURING OF INTESTINE.

The patient was a man of 40 years of age, with a strangulated hernia for five days, and when he first came under the doctor's care, the sac and hernia were gangrenous. The sac had already been opened by a physician. One week after admission, when a line of demarkation had formed between healthy and unhealthy tissue, the adhesions were separated, a fresh section made, and end-to-end approximation of the bowel performed and maintained by suture of the mesentery, mucous membrane, and of the serous surface. There was complete recovery without complication.

Dr. A. B. Kirkpatrick, of Philadelphia, described a new applicator for introducing medicaments into the urethra, uterus, and rectum, which is made of aluminum, silver, or hard rubber, and consists of a cylinder of about 8 inches long, with an accurately adjusted piston. The author had found that a powder of iodoform, boric acid, morphine, and atropine, introduced by this applicator, was almost a specific in acute gonorrhea.

A NEW METHOD OF TREATMENT FOR STRICTURES OF THE RECTUM.

Dr. Joseph B. Bacon, of Chicago, read a paper on this subject. The operation consists in performing celiotomy in the Trendelenburg position. The rectum is exposed and the male half of the Murphy button is introduced into the sigmoid end, and the female half introduced on a staff through the anus and to the proper position in the rectum, an anastomosis thus being made around the strictured portion. In the application of the button, the portion in the sigmoid is sutured, but in the rectual half, a small opening is made in the bowel wall, and the cylinder crowded through and the button clamped.

Dr. W. P. Verity, of Chicago, read a paper on

COMPOUND FRACTURES OF THE SKULL,

which was illustrated by drawings.

Dr. E. A. Tracey, of Boston, described a new material for surgical splints and jackets, and a method of applying it. Wood-pulp is the material that he employs, prepared in sheets, and from them suitable patterns are cut.

---

SECTION ON PRACTICE OF MEDICINE.

---

Dr. Charles G. Stockton, Buffalo, N. Y., Chairman.

Dr. George W. Webster, Chicago, Ill., Secretary.

The first paper read was the Chairman's Address by Dr. Stockton, entitled

A REVIEW OF ULCERATIVE ENDOCARDITIS.

He said that a few years ago endocarditis was considered a simple inflammation of the lining membrane of the heart.

After Osler's lectures in 1885, it became clear that the disease was sometimes infectious, and endocarditis was spoken of as acute, chronic and malignant and ulcerative. In relation to rheumatism, reference was made to the chemical theory of Prout and the nervous theory of Mitchell, but the disposition was manifested to accept the germ theory as being more rational. From the known facts it was concluded that endocarditis may, under favorable conditions, arise from any one of a multiplicity of special causes, and that its course may be as variable as the causes are dissimilar. Of the two classes, malignant and non-malignant, the paper dealt with the former. Ulcerative endocarditis depends upon the presence of a micro-organism that generally attacks the endocardium as the result of some preceding affection. Some forms of micro-organisms have the apparent faculty of inducing endocarditis in the healthy organism, and are regarded as special to this form of disease. Weichselbaum has discovered four such organisms; Fraenkel and Saenger haxe described one, and Lion and Girode still another. The bacillus coli communis has, in some cases, been the active agent in the development of this disease. A case has been reported by Dr. W. T. Howard, Jr., in the *Johns Hopkins Hospital Bulletin* for April, 1893, in which malignant endocarditis was found to depend upon a bacillus having morphologically and culturally the characteristics of the bacillus of diphtheria, although the patient presented no history of having had diphtheria. Different micro-organisms produce different pathologic chemical results. Some organisms invade the mitral and some the aortic valve by preference. Careful observations show that the main valves are first invaded. According to Saenger, the valves in a pathologic state contain vessels in which colonies of bacteria are found, so that the process may be primarily intravalvular; but in many cases the disease appears upon the free surface of the valves.

In Taylor's series, in 11 of 53 cases of endocarditis the lesion occurred on the right side. Lion suggests that aerobic bacteria grow best in the arterial blood of the left side, and anaerobic in the carbonized blood of the right heart. The opinion was expressed that cases of malignant endocarditis recover, and that it is a mistake to apply the term simple endocarditis to all cases that have a favorable termination.

Dr. J. G. Truax, of New York City, had seen 13 cases of ulcerative endocarditis which were fatal. Most of his cases

had articular rheumatism. In two-thirds of them a mistake in diagnosis was made, and the true condition made known by autopsy.

Dr. Henry D. Didama, of Syracuse, dwelt upon the experiments of Richardson, who, he said, produced not only articular rheumatism, but also endocarditis, by injections of lactic acid.

Dr. H. J. Herrick, of Cleveland, Ohio, maintained that endocarditis was a secondary form of disease, and that if the blood was in perfect condition, there could be no endocarditis. Treatment should be directed to the predisposing cause.

SOME CONSIDERATIONS BEARING ON THE TREATMENT OF PNEUMONIA,

by Dr. W. H. Washburn, of Milwaukee, Wis. The author said that the death-rate of pneumonia was gradually on the increase in this country under the present methods of treatment. As long as physicians were unable to destroy the *materies morbi* of the disease, all efforts at treatment were but palliative. Support of the nervous system and elimination of the specific poisons of the disease and the products of retrograde metamorphosis were the indications for treatment. Alcohol was to be regarded not as a stimulant, but as a sedative.

Dr. R. H. Babcock, of Chicago, contributed a paper entitled

THE MEDICAL ASPECTS OF EMPYEMA FOLLOWING OR COMPLICATING CROUPOUS PNEUMONIA,

in which he said that, owing to its insidious onset, purulent pleurisy was frequently overlooked. He would especially call attention, as supporting this belief, to the vague and general manner in which the disease was treated by most of the text books. In many instances the disease was secondary to some pre-existing affection, especially croupous pneumonia and influenza. If due to the presence of the pneumonia coccus, there was a great tendency to spontaneous evacuation through the bronchi.

He recognized four types of empyema. The prognosis in the form of pneumonia due to the pneumonia coccus was good. Such cases usually yielded to simple puncture and drainage. The other forms indicated a graver prognosis, and required more active surgical intervention.

Dr. W. A. Batchelor, of Milwaukee, said the treatment of empyema should consist in incision and drainage. Many cases could be cured by aspiration, and he believed that bacteriological investigations of pleurisy would lead to better methods of treatment.

Dr. Martine, of New York, held that the reduction in the pulse rate in cases of pleurisy would prevent empyema.

Dr. George W. Webster, of Chicago, had treated seven cases of empyema, in persons ranging in age from 3 to 40 years, within the last sixteen months, by washing out the pleural cavity with a saturated solution of boric acid. All of the cases recovered.

---

JUNE 7TH—SECOND DAY.

POINTS IN THE CLINICAL HISTORY OF ERYSIPELAS,

by Dr. J. M. Anders, of Philadelphia. Attention was directed to the influence of the various seasons of the year upon the disease. The author collected a large number of cases from hospital and private practice, and after careful study found that the largest number of cases occurred in April, and that from April to August there was a gradual decrease in the number. More than one-half of the cases collected occurred under 30 years of age, and these were largely between the ages of 20 and 30. Of 1787 cases, 1239 were males and 548 females. Slight wounds and contusions of the face and head were exceedingly common as starting points of the disease. In only 7.8 per cent. was the affection secondary to chronic disease. The author said that the average duration of the affection in over one thousand cases was twenty-five and one-tenth days; that if the individual was in an enfeebled condition the duration was longer. Relapses occur in about ten per cent. of all cases.

Dr. H. A. Hare, of Philadelphia, said that erysipelas was quite frequent in cases of pronounced nasal and buccal lesions. In typhoid fever, for example, such lesions afforded entrance to the specific organisms of the disease.

DEMONSTRATION OF GASTRODIAPHANY,

by Dr. Max Einhorn, of New York City. One of the objects of the paper was to point out the great difficulty of making a

correct diagnosis of abdominal disease, more particularly in the case of the stomach, which was the organ most frequently diseased. The apparatus exhibited by the author consisted of a soft rubber tube, to which was attached an Edison lamp. The apparatus can be introduced into the stomach with no more difficulty than is required in introduding the ordinary stomach tube. The patient must be in a fasting condition, and immediately before the passage of the tube, should be given one or two glasses of water. The author exhibited two patients and demonstrated the working of the apparatus.

Dr. John Aulde, of Philadelphia, alluded to the value of translumination in the diagnosis of laryngeal disease, particularly in young subjects, and said it might be of value in gynecic and rectal disease and abdominal surgery as an aid in diagnosis.

Dr. Joseph Eichberg, of Cincinnati, followed with a paper entitled

A CASE OF SUNSTROKE, WITH CONSIDERATIONS OF ITS TREATMENT.

The true pathology of sunstroke had not yet been determined, although it was known that there occurs a disturbance of the heat regulating center. The prognosis was influenced by the degree of cerebral activity. Treatment consists in reduction of the temperature by external applications of cold, and the administration of digitalis or the hypodermic injection of digitalin to stimulate the heart muscle.

THE TREATMENT OF INSOLATION,

by Dr. R. R. Ross, of Buffalo, N. Y. The author did not dwell on all that is conveyed by the term thermic fever, but confined his remarks to sunstroke. He said that high degrees of temperature might be borne if the air was dry, because he considered sunstroke very rare in dry hot countries, and that those who had clean skins and a good vasomotor system were less prone to it. The prophylactic treatment consisted in cleanliness and the avoidance of mental and physical exhaustion. He looked upon antiseptics as useless and dangerous, for the reason that they may produce heart failure and exert a destructive influence upon the blood corpuscles. An important point in treatment was the reduction of the temperature. He thought it was wrong to pack the patient in ice, on account of the shock that results. The temperature of the bath should be 45 or 50, and the patient should be immersed for two or three minutes, the head being cooled as rapidly as the body. He recommended rubbing the skin with a coarse towel, and having the process repeated. Atropine, sulphuric ether, camphur and strychnine he uses according to circumstances. In the case of convalescents a diet of liquid and farinacious food should be adhered to.

Dr. Hare, of Philadelphia, was inclined to doubt that the danger in sunstroke was due to conbustion, believing that it was due to the change that takes place in the nervous system.

Dr. N. S. Davis, Jr., of Chicago, read a paper entiled

SOME REMARKS ON DIABETES.

in which he advised in the treatment the use of Clemens' solution, except in the more advanced cases. Unless the desired therapeutic effect was obtained before, the dose should be increased to toleration. Doses of 6 or 8 minims were usually sufficiently large. The use of arseniate of strychnine had proved efficacious in his hands. He had tried pancreatic extracts, but had found them of doubtful value.

Dr. Didama, of New York, cited a case in which treatment with pancreatic extract was entirely useless.

HEADACHE,

by Dr. James W. Putman, of Buffalo.

The author first considered the part played by heredity in a given case of headache, and secondly dwelt upon the personal history as regards syphilis, dyspepsia, etc. After the above had been considered, the history of the headache should receive attention, when, and under what circumstances it came on. The character of the headache itself was then to be observed, its periodicity, location and characteristics. The author then discussed the anemic and congested classes of headache, together with the methods of treatment. He said that reflex headache from eye-strain was common, but oculists failed to afford relief owing to imperfect correction of the ocular defects.

Dr. J. T. Whitaker, of Cincinnati, said that eye strain was not such an important factor as a great many physicians had supposed.

AN ADDITIONAL NOTE ON THE TREATMENT OF EXOPHTHALMIC GOITER.

by Dr. E. D. Ferguson, of Troy, N. Y.

The author said that the 15 or 20 cases that had come under his care since a previous report had markedly improved under treatment with strophanthus, and there had been no relapses. He recommends for the initial dose 8 or 10 drops, three times daily, but the dose varies in different cases.

Dr. Hare, of Philadelphia, said he had never found strophanthus to act well, but that occasionally it causes severe diarrhœa.

Dr. Anders, of Philadelphia, said that when strophanthus was used alone it did not give good results. If arhythmia existed however, strophanthus and digitalis combined regulated the action of the heart much better than either of the drugs when used alone.

THE MUTUAL INTEREST OF THE MEDICAL PROFESSION AND INSURANCE COMPANIES IN THE PROLONGATION OF LIFE

was the title of a paper read by Dr. Charles Denison, of Denver, in which he did not advocate the insurance of invalid risks, but believed that the time would come when a better understanding of the varying longevities of invalids might lead to a knowledge of their insurability. The author believed that latent tuberculosis was the cause of more failures in health than was usually supposed, and urged the employment of systematic safeguards against accepting such lives on an equal footing with selected healthy risks.

Dr. John H. Hollister, of Chicago, in a paper entitled

THE TREATMENT OF CHOLERA,

accepted Koch's bacillus as the cause, and said that one of the most important problems was to prevent the transfer of this organism from one person to another. A certain means of safety was the sterilization of everything coming from the sick. Opium was now repudiated in the treatment. Hypodermic injections of thymol had proved very successful. Of all drugs perhaps there was no one more highly extolled than tannic acid, given by rectal injection along with large amounts of water.

Dr. J. T. Whittaker, of Cincinnati, Ohio, contributed a paper on

THE PRESENT STATUS OF TUBERCULIN.

The speaker first set forth the reason and methods of its action. Human tuberculosis differed from laboratory tuberculosis. Invasion by micrococci, he said, was often secondary to the tuberculous. As a diagnostic agent, tuberculin was of the utmost service and certainty. In incipient cases it was valuable as a therapeutic agent, and in other diseases when the existence of tuberculosis was masked by unexpected symptoms.

In the discussion, Dr. Denison, of Denver, said he often used tuberculocidin in preference to tuberculin. As a diagnostic agent he especially commends its use.

---

JUNE 8TH—THIRD DAY.

The first paper read was by Dr. Henry D. Didama, of Syracuse, entitled

BRIEF CLINICAL MEMORANDA.

In the first place saliva is an excellent substitute for olive oil, glycerine, cosmoline or other substance as a lubricant for catheters. Although containing bacteria, saliva is not septic and is always at hand. Second, in preparing hemorrhoids for injection he anæsthetizes by means of ether or the A. C. E. mixture, and follows by digital dilatation of the anus. He then brings down the hemorrhoids, ligates those with small pedicles, tying with a bow knot, and then injects the material to be used. Third, he recommends the following facile reduction of prolapsed hemorrhoids: The patient is placed on his back with his knees drawn up. Cocaine is applied to the hemorrhoids if tender. These are then thoroughly lubricated with vaseline, and with the tips of two or three fingers pressed up while the patient at the same time is directed to bear down. The hemorrhoids readily slip up into the bowel. The patient himself can perform this operation without the aid of a second person. Fourth, for the ready relief of lumbago, the author has for ten years or more employed large dry cups over the entire lumbar region. Four cups are applied at once, and the application is repeated. In fifteen minutes the pain is entirely gone.

In the discussion of the paper Dr. Frank Billings, of Chicago, said the patient was in constant danger of infection from the use of saliva as a lubricant. He believes that saliva frequently contains pathogenic and pyogenic bacteria.

Dr. Charles Denison, of Denver, said there was danger of transmitting tuberculosis by the saliva when used as a lubricant. He also believes that it frequently contains tubercle bacilli.

Dr. John Aulde, of Philadelphia, laid stress upon the rheumatic origin of lumbago. He recommended the use of the iodide of potassium and the salicylates, as well as the faradic currents.

Dr. Joseph Price, of Philadelphia, considered appendicitis one of the most troublesome conditions met with by both gynecologists and abdominal surgeons. He takes the ground that the condition is purely a surgical one, and advises operative interference in every case.

Dr. Whittaker, of Cincinnati, preferred the word typhlitis to appendicitis, and said that no physician would object to operation in cases in which ulceration was present.

Dr. Joseph Hoffman, of Philadelphia, said there was a possibility of a case of appendicitis getting well without treatment, either medical or surgical, but convalescence was prolonged under such circumstances.

Dr. L. S. McMurtry, of Louisville, maintained that many cases of appendicitis were reported in the mortality lists as peritonitis, more particularly those occurring in males.

Dr. J. B. Murfree, of Murfreesboro, Tenn., contributed a paper on

DIPHTHERIA,

in which he said that the greatest number of cases occur between the ages of three and twelve, and but very few in infants. The disease may be transmitted by cows, and the period of incubation is from two to five days. The prognosis was always unfavorable. In the treatment few remedies are of much avail, and none is specific. Isolation and disinfection must be absolute. Antiseptic mouth washes, astringent gargles, the swallowing of ice, pepsin, trypsin, etc., to destroy the membranes; tincture of ferric chloride for the blood; mercuric chloride, alcoholic stimulants, especially large and frequent doses of whiskey, constitute a useful method of treatment.

Dr. E. J. C. Minard, of Brooklyn, followed with a paper on

EARLY ASPIRATION IN ACUTE PLEURITIS.

The diagnosis of the condition is not always easy. The author advised early aspiration.

THE DETECTION AND SIGNIFICANCE OF CARBO-HYDRATES IN THE URINE,

by Dr. Charles W. Purdy, of Chicago.

The remarks of the author were confined mainly to the consideration of glycosuria, for the quantitative determination of which he proposed a new test. The test solution consists of copper sulphate, 48 grains; pure potassic hydrate, 144 grains; strong ammonia, U.S.P., 9 ounces; glycerine, 6 drachms; distilled water, 20 ounces. It was said to be stable and reliable. Some of the blue solution is placed in a vessel and the urine is dropped in from a buret until the blue color disappears, when the amount of sugar present may be estimated.

---

JUNE 9TH—FOURTH DAY.

Dr. H. A. West, of Galveston, Tex., contributed a paper entitled

THE ASSOCIATION OF DISEASES AND MORBID PROCESSES,

in which he directed attention to the difficulty of ascertaining after death the exact morbid condition that was the immediate cause of death. Lowering of individual vitality as a result of famine, over-work, and intemperance is one of the main predisposing causes of various morbid conditions. A widespread disobedience of sanitary laws is the common origin of most of our epidemic diseases. In all acute infectious diseases there is a great tendency to involvement of the respiratory organs, and especially to croupous and catarrhal pneumonia. Cardiac disease is usually indicated by symptoms referrable to other organs, as dyspnœa, digestive disturbance, intesinal or renal derangement. Derangement of the function of one organ will give rise to modification of associated functions elsewhere. If the liver be primarily involved there occurs stasis of the entire portal system, with gastric and intestinal catarrh, constipation or diarrhœa, jaundice, etc. Inherited diatheses predisposed to the development of tuberculosis. Scrofulous and gouty individuals are subject to tuberculosis and lithemia respectively.

Dr. Charles Denison, of Denver, directed attention to the association of fibrosis with tuberculosis. He believes that the so-called tubercles are the vaults in which nature imprisons the tubercle bacilli to prevent their multiplication.

Dr. X. C. Scott, of Cleveland, took the position that disease was not inherited; that a certain state or condition that favors the contraction or developement of certain diseases may be transmitted from parent to child. As long as the general system was in a good condition the individual posesses a certain degree of immunity.

Dr. George W. Webster, of Chicago, maintained that syphilis could be transmitted by heredity.

THE NEW CHEMESTRY OF THE STOMACH AS A MEANS OF DIAGNOSIS AND GUIDE TO THERAPEUTICS, BASED UPON THE RESULTS OF ONE THOUSAND ANALYSIS OF STOMACH FLUIDS,

by Dr. J. H. Kellogg, of Battle Creek, Mich. In this paper the author described a new method of analyzing the stomach fluids, and proposed a new classification of gastric diseases functional in character.

Dr. Charles Dennison, of Denver, exhibited a new syringe for the injection of tuberculin, which he considered much better than the one usually employed. The syringe is marked in minims on one side, and on the other milligrams. The author uses a one per cent. solution for doses under 20 milligrams, and a ten per cent. solution for doses over 20 milligrams.

---

### Everybody Has Seen Her

Do you know the doleful person? asks the *Omaha World Herald.* She, for the doleful person is almost always a woman, is always a good neighbor in health, and tries to be neighborly in sickness. But she makes a miserable failure at the latter. You know how she acts. Don't you remember the last time the baby was sick? After you had watched by the little one's bed day after day and night after night, and watched the roses fade from the little one's cheek, and saw the little one's form waste away? And don't you remember how she tried to cheer you up with a one-sided conversation, something like this:

"Why, Mrs. B—, how much worse the baby looks this morning. She looks just like Sarah Jones' baby did the night before it died."

"Gracious! I never saw a child so wasted away as Sarah's was, except yours. We just done everything for the child, but it wasn't no use."

"I never will forget how Sarah took on at a funeral!"

And the doleful neighbor suddenly remembers that she has to run back home to "set a sponge," and when she goes you hope she will never return. You look again at the suffering babe and feel that your heart must surely break.

But suddenly there is a knock at the door, and in comes the—well, sun-beam neighbor, is as good a name as any. She was over the evening before and quietly and unobtrusively helped to do so many needful things, and when she left, she left a word of cheer. And when she comes this time she says something like this:

"Why, how much better the baby looks this morning!"

And don't you remember what a bright gleam of hope crossed your mind?

"I never saw a child improve so much in so short a time before. I am sure the baby will soon be well."

And then the sun-beam neighbor re-arranges the bed, adjusts the blinds, tells you she will call again in a few hours, and hurries home.

Honest, now, didn't she leave a confident feeling behind her? She felt better and more hopeful. Baby, even, seemed to rally under the words; and when at last the little one was playing around your knee again, didn't you think of the words of the sun-beam neighbor?

The doleful neighbor has frightened more mothers to death, buried more babies and caused more tears than all the plagues combined.

She should be suppressed.

---

The man who never praises his wife deserves to have a poor one.

---

Masturbation, according to Prof. Parvin, is of rare occurrence in the female sex, the percentage being only about three-tenths of one per cent., whilst among the male sex it is about three per cent.

ISSUED EVERY SATURDAY

ADDRESS
Care P. O. Box 843, Philadelphia.

HAROLD H. KYNETT, A. M., M. D.,
Editor.

RODERIC C. PENFIELD,
Publisher.

316 - 18 - 20 North Broad Street,
PHILADELPHIA.

**TERMS**:—Five Dollars a year, strictly in advance, unless otherwise specifically agreed upon. Sent three months on trial for $1.00.

**REMITTANCES** should be made payable only to the Publisher, and when in sums of Five Dollars or less, should be made by Postal Note, Money Order or Registered Letter.

**NOTICE TO CONTRIBUTORS**:—We are always glad to receive articles of value to the profession, and when used they will be paid for, or reprints supplied, as the author may elect. Where reprints are desired, writers are requested to make a note of that fact on the first page of the MS. It is well for contributors to enclose stamps for postage, that the articles may be returned if not found available.

SATURDAY, JULY 8TH, 1893.

## EDITORIAL.

### PREVENTIVE MEDICINE.

The address of Mr. Ernest Hart, of London, before the American Medical Association at its recent meeting, demands the attention of the whole medical fraternity. With startling clearness, he shows the relation of Cholera to the water supply and presents a mass of evidence that cannot be put aside or argued away. London, with its enormous population, and with its water supply divided between several companies, each drawing from a different part of the stream, presents an experiment which it would be hard to duplicate. The lesson is plain and the words of the text are written in human lives, sacrificed silently, without the knowledge that they were yielded up for any great cause, without the glory of war, without the religious enthusiam of the martyr; and yet they were martyrs in a cause greater than that for which men have fought and suffered—the prevention of disease and plague.

Medicine is only now coming out of the mist and darkness of the mediæval age and is only now grasping the idea that plagues are preventable. The old notion that they were beyond human control, that they were due to a diabolical agency against which it were folly to struggle with any weapon; or the later vague theory that they were due to a subtle miasmatic influence as uncontrollable as the wind on which it was borne, is giving way to the clearer light of scientific research and now we know that it is man himself, not the devil, not any breath of wind, to which we must look for the cause of pestilence.

When a great epidemic threatens, the cry goes up from the press of the land, medical and lay, for clean streets, clean houses and pure water, but after the danger is over there is only too much probability that the press will be silent and, like faithless sentries, sleep till the footsteps of the hostile army grow so loud that even the deaf sentry must wake. In an army, with the enemy within marching distance, such a guard would be unknown. Why should it be so in medicine, where

the fight is not against a human foe but against a foe that is all the more deadly because unseen and sleepless.

If cholera had reached our city, and the deaths had amounted to anything like the ratio that there has been from diphtheria during the past winter, the town would have been deserted and the people panic stricken. But typhoid fever and diphtheria are diseases which we have gotten used to and take as a matter of course; perhaps, as with the diphtheria, quarantining those suffering with the disease and, ostrich-like, burying our heads in the sand of a quarantine, thinking that we are safe. Of what use is quarantine while the source of the disease, filth, is allowed to remain.

At one time the northwestern part of the city was a hot-bed for typhoid fever, and the hospitals in that section were full to overflowing with cases of the disease. The cause was not far to seek. That portion of the city was supplied with water from the Delaware, while the rest of the city received its water from the Schuylkill. The Delaware is a tidal stream, the sewage of the city empties into it; and, although the inlet for drinking water was above the outlet for sewage, the supply was polluted, and lives were lost in consequence. With the change of supply the typhoid almost wholly ceased.

The great illustrations of the value of preventive medicine come from the cities, for there men are herded together, and the danger of infection is greater. But how often does it happen that typhoid breaks out in the farmer's family—the result of neglect of sanitary laws. The people are hard to convince, and it is only when the matter is brought home by some terrible lesson that they will hear. Too often the patient says, "My grandfather drank from this well, and what was good enough for him is good enough for us," forgetting all the while that the community has increased in numbers, and what was a lonely farmhouse in the midst of broad fields has become the centre of a village.

People love liberty, and liberty of thought and action are the cornerstones of our country and her institutions. Therefore people resent what they term prying into their business, even in the matter of sanitation. They must be taught that it is not only for their neighbors' good, but their own, that they are compelled to abate nuisances. Liberty of action does not include danger to one's fellows.

Medical men must not fold their hands and keep silent. To a large extent they are the educators of the people; to them the people look for guidance in matters of health, and through them must the people be made to understand that certain diseases are preventable, and that if each will see that "his own front yard is clean," he and his neighbor will fare better.

Smallpox has been almost rooted out. Typhus is almost now unknown; and so may it be with other diseases if we but put our shoulder to the wheel as guardians of the nation's health. A great duty devolves on the board of health of the community. Generally, they are men of honesty of purpose; but too often the office is a convenient resting-place for the weary political worker or his crony, and the post is filled by men who know nothing of sanitation, and who care only for the paltry honor and perquisites of the position. Such things ought not to be, and the sooner the position of member of the board of health is taken out of the hand of politics and made honorable, the better it will be for the communities at large. The sooner medical men preach the great gospel of cleanliness in daily life and the importance of prevention, the better will it be for the public health. Cholera has probably been prevented from visiting this country, but there are other diseases against which we must keep up the struggle of prevention. Therefore, watch!

# BACTERIOLOGICAL NOTES.

## The Bacillus of Diphtheria (Klebs-Loeffler Bacillus.)

Although several species of bacteria, including micrococci and streptococci, have been attributed with more or less evidence as the etiological factors in diphtheria, the Klebs-Loeffler bacillus is now generally accepted as the cause of the disease. This germ was first described by Klebs in 1883. He found it the diphtheritic membrane but did not succeed in isolating it. In 1884 Loeffler obtained it in pure culture and since that time it has been known as the Klebs-Loeffler bacillus and its etiological value has been demonstrated by a large number of investigators.

Morphologically this bacillus varies very considerably. The rods are straight or slightly curved with ends rounded. They have a diameter of from 0.5 to 0.8 micromilleters and in length vary from 1.5 to 3 micromillimeters. One end of the bacillus is frequently club-shaped and irregular, forms which are almost, if not quite, characteristic of this organism. In an unfavorable culture medium the forms are especially varied, one or both ends being thickened or an expansion in the central portion of the bacillus. Occasionally the rods appear to be made up of irregular oval or spherical segments. No spores have been observed and the bacteria do not grow in filaments. It is stained with the ordinary aniline dyes. It takes the Graus stain. In order to demonstrate the bacilli in diphtheritic membranes, Welch and Abbott state that "Nothing can surpass in brilliancy and sharp differentiation, sections stained doubly by the modified Weigoit's fibrin stain and picrocarmine." In cover-glass preparations from the membrane the diptheria bacilli can be quite readily distinguished, especially if the Graus stain has been used.

Biologically, the diphtheria bacillus is *aërobic* and *faculative anaërobic.* It develops in various culture media at a temperature varying from 20°-42°C. The most favorable temperature being about 35°C. On nutrient agar the colonies are of a grayish yellow color, their outlines are not sharply defined and a rough almost reticulated surface. The growth is not very rapid. It grows in gelatine but does not liquify it. In bouillon it imparts a uniform cloudiness to the liquid; occasionally, however, the growth is in the form of whitish masses along the sides and in the bottom of the tube. The growth on potato has been questioned but Welch and Abbot found that it did develop on ordinary steamed potatoes. This bacillus develops in milk and, as it grows at a low temperature, it may be easily communicated from one person to another through this medium.

The bacillus of diphtheria retains its vitality in cultures for several months. It has been known to live for nine weeks in dried fragments of the diptheritic membrane. It is destroyed by heat at a temperature of 58°C. after an exposure of ten minutes.

The bacillus of diphtheria is fatal to rabbits, guinea-pigs and cats. Rats and mice are remarkably immune to inoculations of this germ. When rabbits or cats are inoculated in the trachea with cultures, a characteristic diphtheritic inflammation is produced, which is followed with general toxemia and death, from the absorption of soluble toxic products formed at the seat of inoculation. This has been and still is believed to be the cause of death in the human species suffering from this disease. This is evidenced by the large number of bacteriological examinations that have been made with negative results from the blood and organs of animals and people who have perished from this disease. That bacteria are only found at the point of inoculation has been the accepted belief. This fact renders the recent discoveries of Frosch and others, of the diphtheritic bacilli in the various organs of the body, of considerable importance in throwing light upon the possible range of distribution of these bacteria within the body.

The length of time during which the bacilli retain their vitality and their power to develop so abundantly in milk are facts worthy of consideration in the isolation of cases and the preventive treatment of other members of the family. The localization of the bacteria on the mucosa of the mouth and pharynx renders the marvelous results which have been reported by local antiseptic treatment quite possible.

### A Contribution to the Pathology of Experimental Diphtheria, with special reference to the appearance of Secondary Foci in the internal organs.

Abbott (*Bulletin of the Johns Hopkins Hospital*, IV. 1893, p. 29,) gives an account of some very interesting alterations produced by the bacilli of diphtheria. In addition to the lesions usually found in experimental animals as indicated by the investigations of Welch and Flexner (ibid II. 1891, p. 105,) Dr. Abbott describes the special lesions in the omentum "which consist in minute yellowish, lens-shaped foci, usually between the peritoneal layers and usually circumscribed in outline." "When visible to the naked eye they are rarely larger than the eye of a small cambric needle, and of about the same shape. They are occasionally larger than this, but more commonly smaller, being frequently so small as to be detected only by microscopic examination of sections of the hardened and embedded omentum. As a rule the omentum containing these bodies is somewhat congested, and often presents a shriveled appearance at its free margin. It is in this free margin that the foci are most commonly to be found. Upon microscopical examination these nodules are seen to be sometimes very sharply circumscribed, while again they are slightly less regular in outline. At times they may be seen lying between the folds of the peritoneum, while again they will be limited to the walls of lymphatic spaces. Upon closer examination they are seen to consist of polynuclear leucocytes and those having the horse-shoe-shaped nucleus closely packed together. The majority of the leucocytes composing the nodules contained bacteria which in their morphological and staining peculiarities were identical with the bacilli of diphtheria." In one instance pure cultures of virulent diphtheria bacilli were obtained from an unusually large nodule. The histological structure of the nodules is simple, consisting of masses of leucocytes, many of which are in the phagocytic condition.

Until comparatively recently, the opinion in regard to the relation of the diphtheria bacilli to the organism in which they are located has been that they remained at the point at which they had been deposited, but recently evidence has been obtained which will cause a modification of the original theory of localization. Frosch (*Zeit f Hygiene*, 1893, p. 49-52.) has reported the discovery in the internal organs of diphtheritic bacilli in 10 out of 15 fatal cases of the disease. The way in which the bacilli gain entrance to the internal organs is not known, but Abbot believes that the evidence now at hand indicates that their invasion is accomplished by means of the phagocytic cells.

---

### Acute Ulcerative Endocarditis Due to the Bacillus of Diphtheria.

Howard (*Bulletin Johns Hopkins Hospital*, iv. 1893, p. 30) records a case of acute endocarditis due to the diphteria bacillus. The affection was in a man aged 44. It began with a chill, high fever, pain in the head, abdomen and limbs. The disease ran a course lasting seventeen days. The endocardium was found to be rough, ulcerated and hemorrhagic. The spleen, liver and kidneys were diseased. Cover-glass preparations, made from a thrombus-mass on the mitral valve and from the spleen and kidneys, all showed the presence of a bacillus with all of the morphological characters of the bacillus of diphtheria. This bacillus was the only organism found. Tubes of glycerine agar were inoculated from the mitral valve, the lungs, the liver, spleen and kidneys, all of which developed pure cultures of this bacillus. This germ has been studied by Prof. Welch and Dr. Abbott, as well as by the author, and the only point in which it was found to differ from the diphteria bacillus was its failure to kill experimental animals. The microscopic examination of the tissue showed the bacilli to penetrate to the depth of only two to three layers of cell in the endocardium. The histological study of the organ demonstrated the fact that the bacillus concerned in the lesions present is to a certain extent a pus-producing organism. There was a decided hyaline degeneration noted in the muscle tissue of the valves of the heart. As the author states, "the striking points in this case are a malignant endocarditis with general infection caused by a bacillus that is morphologically and by culture methods indistinguishable from the bacillus of diphtheria." Here we have not only a wide distribution of the bacilli in the body, but the primary lesion situated in a very unusual place (endocardium). Although this bacillus failed to kill guinea

pigs, others have found the Klebs-Loeffler bacillus unable to destroy these animals. According to Prof. Welch, this is the first time that the bacillus of diphtheria has ever been found to be the cause of ulcerative endocarditis.

# TRANSLATIONS.

## TOXIC JAUNDICE DUE TO INFECTIOUS DISEASES.†

and that the mechanism of its production is simple enough and readily understood. Its pathogeny, however, is more compli-

Rendu, in treating of this subject (*Le Bull. Med.*, May 28, '93) says that simple catarrhal jaundice has probably some intestinal complication as its point of origin, cated. Very probably, as Chanffard has first shown, it is due to an attenuated and benign affection, but nothing definite can be stated. However, there exist other forms of jaundice, truly infectious in nature, which follow in the course of general diseases and which are very difficult to explain. He reports two cases, one occurring in a woman of 67, who appeared to be suffering with a pneumonia of the apex, and in whom a jaundice supervened without any obstruction of the biliary passages, and the other in a man 32 years of age, who developed a marked jaundice in association with a facial erysipelas with cerebral complications, but without obstruction of the bile-ducts.

Such cases undoubtedly have a certain connection with malignant jaundice. This question of pleiochronic jaundice, as it has been called, is a very complex one, as yet unsolved. Anatomically there exists a very great difference between these patients and those with catarrhal jaundice, namely, that in the former the biliary passages are absolutely permeable. This is a capital point on which are based fundamental clinical differences, viz: the colored robes, at times the bilious diarrhœas, the urine more or less deeply pigmented, but less than in jaundice by obstruction. A second difference consists in the almost complete absence of hemorrhage in the two cases reported, while grave jaundice is accompanied, so to speak, invariably with hemorrhage of the skin and mucous membranes, particularly with melena and epistaxis. We cannot consider as hemorrhagic manifestations the several ecchimotic *taches* which the female patient presented on her wrists, nor the insignificant drops of blood which constituted an attempt at epistaxis in the second patient.

Rendu insists upon the point that at the base these jaundices that are allied to the infectious diseases have close affinities with malignant jaundice. They are not *per se* of the nature of grave jaundice, but they become such by virtue of their concomitant visceral complications, notably the renal complications. This law is verified in the two cases reported. In both the kidneys were functionally bad, the urine scanty and albuminous. In this form of jaundice he claims that the renal lesions are, so to speak, the key to the problem. The biliary poisoning adds to itself a poisoning of urinary origin; the kidneys become unable to eliminate the poisons and become altered, the more in proportion as the impregnation of their epithelium by the bile is older and more profound. The kidney, however, is not alone in the causation of the rapid evolution of the malignant jaundice. The lesions of the liver play a certain important role. This fact cannot be doubted when we find, as in the second patient, the lesions of cirrhosis and interstitial hepatitis. But the alterations are not always evident, and in fact the liver may appear almost healthy, aside from the biliary impregnation. That which is important to bear in mind is that in this variety of jaundice the poisoning of the economy is always of a complex origin, and that the patients do not succumb only to biliary poisoning. It is well known besides, as proven by the experiments of Vulpian, that injections of bile are relatively but slightly poisonous. This will explain the long persistence of certain forms of chronic

† Translated for The Medical and Surgical Reporter, by W. A. N. Dorland, M. D.

jaundice which only moderately alter the general health.

An interesting point is the frequent association of pneumonia and jaundice. Grisolle, long ago, remarked that pneumonia of the apex very frequently accompanied the grave forms of jaundice, a statement that destroys, by the way, the theory of hepatitis by continuity. Gubler, in 1872, showed that usually in pneumonia the jaundice is not biliary but hemapheic—the theory of blood jaundice. He explained it by the exaggerated destruction of the blood corpuscles, causing the escape into the blood of too much unused hemoglobin, thus giving rise to a coloration of the tissues—a greenish yellow. It is admitted that the microbes of the affected part secrete a poison which is absorbed in a different manner by the tissues and thus determines variable irritative lesions. Whatever may be the form of poison, it is interesting to know how the jaundice is produced under its influence. Three hypotheses may be advanced: either the blood corpuscles are destroyed in the blood and the biliary pigment immediately formed; or, the irritated liver secretes bile abundantly, with a polycholia and biliary infiltration of the tissues; or, finally, the later view, there is an obstruction to the intra-hepatic biliary circulation due to an obstruction of the inter- and intralobular biliary canaliculi. The first hypothesis cannot be sustained, as Stern has demonstrated. The second hypothesis, that of a primary polycholia, due to toxins which penetrate into the liver, appears to Rendu to be an expression of the truth, at least in the greater number of cases. It is, moreover, proved clinically and experimentally.

The treatment of these morbid states, unfortunately, belongs to theory rather than to practice. Theoretically, the toxins should be driven out without debilitating the patient. Here is the difficulty of the problem. Purgatives, and especially drastic purgatives, are contraindicated on account of the great prostration they induce. Sudorifics, as pilocarpin, are not without danger, on account of the bad state of the kidneys. Our resources are very limited. Rendu thinks the better plan consists in utilizing the natural reactions; hot drinks, tea, coffee, which provoke at once diuresis and diaphoresis, while stimulating the nervous system; injections of caffeine, which especially answers for the last indication, are, without doubt, valuable; finally, milk diet and careful regime for the alimentation of the patient. Best of all is to envelope the patient in a wet jack to induce diuresis and perspiration. This may be continued for a full hour without danger.

## A REPORT OF FIVE CASES OF CONGENITAL STRICTURE.*

The author (Dr. Werner, of Markgrönigen,) reports, in detail, five cases, which have come to his notice during a practice of 40 years. He has never seen a complete imperforate anus.

The first case, which happened in 1867, a child aged 20 weeks, had suffered from birth; defecation being extremely painful and covering a long period of time, owing to the small opening.

The author made a small incision with a bistoury having a blunt end, and enlarged the incision with scissors, introducing a catheter at once incited the bowel to action; the lower bowel was thereby emptied. Three days later the child, having had no movement during the interim, was again suffering considerably; and it became necessary to resort to injections and the use of the catheter, which again gave relief.

One month later the mother reported that the child was well, excepting that it was necessary to use the injection daily.

In February, 1891, the author states that the former patient married and had two (2) children, and two years after the operation she was able to do without the injection, and that now she is enjoying perfect health.

Case II. Seen in 1879, age 5 months; always seemed to have pain on defecation, which had always been thin, Four days before, being seen, she had begun to discharge small, round balls of fecal matter, causing great pain. A female catheter

*Translated for THE MEDICAL AND SURGICAL REPORTER by Marie B. Werner, M. D.

was easily inserted; after being passed 3½ c. m. seemed to come in contact with a constriction. A further examination with the little finger proved the presence of an unmistakable stricture.

The author performed a successful operation, which he gives in length; the child recovered promptly, was found enjoying good health in 1891.

Case III. Seen first January, 1891, aged 11 months; has been suffering since birth from difficult defecation. Operation same as case second; prompt recovery.

Case IV. Seen first August, 1878, aged 9 weeks, and had had two previous operations; previous diagnosis, complete closure of the rectum, which the author seems to doubt. An operation seemed to be successful, as in others. The communication received 13 years later said, however, that the boy is well developed, mentally sound, but that up to his seventh year had had no control over the sphincter ani; and even now cannot retain any liquid movement. An investigation of the parts shows a patulous opening, size of a cherry stone, large enough to admit an ordinary lead pencil; in passing the finger into this opening, one reaches an obstruction, in all probability a healthy internal sphincter. The child suffers no pain and never passes blood or mucus.

Case V. Seen in January, 1889, the child 2½ months old, which was so sick and emaciated that an operation was out of the question, died several days after being seen.—*Memorabilien*, May, 1893.

## A CASE OF FRACTURE OF THE HUMERUS IN A CHILD ONE DAY OLD.*

Gurlt has shown in a statistical table, comprising fourteen hundred cases (prepared by B. Gerber, *Gyoyazat*, No. 14, '93), that the above-mentioned fracture occurred but in five children who had not yet reached their first year. Of these five, there were three cases of fracture of the femur, one of the scapula, and one of the clavicle; none were recorded of the upper extremities.

Dr. Gerber's case is for that reason, a rare as well as an interesting one. On the 10th of December, '92, he was called to see a child, the complaint being made that it could not lift the left arm. A careful examination revealed a normally developed baby whose left arm, at about its upper third, was crooked, crepitation being easily demonstrated, showing the bone to be completely fractured. Reposition of the ends was produced by decided conuler extension. The entire arm is then encircled by a broad bandage, over which a splint made of heavy paper was properly adjusted, allowing the position of the arm to be at right angles, and then bandaged to the body after careful protection with cotton. The bandage was removed every seven days. After the removal of the second bandage there was sufficient callus thrown out, making the union at that early date secure. With the exception of the first few days, when a slight œdema of the fingers and hand was present, and which was removed by a gentle massage, the fracture healed thoroughly in three weeks, with no untoward symptoms.—*Der Kinder Arzt*, May, 1893.

## CORRESPONDENCE.

### Epistaxis.

TO THE EDITOR OF THE MEDICAL AND SURGICAL REPORTER:—Sir: Permit me to testify to the efficacy of the methods of staying epistaxis, recommended by Dr. Phillips in your issue of the 6th of May, p. 709. The method has been long known and practiced in Dublin. We ascribe its introduction to Mr. Josiah Smyly, from whose son, Mr. (now Sir Philip), Smyly, I learned the method as a student of the Meath Hospital of this city.

Yours truly,
GEORGE FOY.

7 Cavendish Row, F. R. C. S., Rutland Square, East, Dublin.
June 9th, 1893.

# ABSTRACTS.

## HINTS TO PREVENT THE SPREAD OF CONSUMPTION.

Wm. R. Huggard, of Davos Platz, Switzerland, sends the following: All cases of tubercular disease of the lungs ("consumption") take origin directly or indirectly from other cases. This is now an established fact. Infection, however, is easily provided against if certain simple precautions are taken.

The chief modes of infection are:—

1. *By inhaling dried and pulverized expectoration.*

This is apt to occur when an ordinary pocket-handkerchief is used by a tubercular person for expectoration. When such a handkerchief is opened, the dried expectoration is likely to be pulverized and diffused through the air. Thus it may be inhaled by others, as well as by the patient himself, who is likely to suffer from drawing disease-germs into portions of lung previously unaffected.

Another source of pulverized expectoration is the habit of spitting on the ground. The expectoration becomes mixed with dust, and then is easily carried into the air. This habit, therefore, is not merely offensive, but dangerous.

2. *By using spoons, cups and other articles of the kind which have not been properly washed after having been used by tubercular persons.*

3. *By kissing.*

This source of infection is especially to be guarded against in the case of children.

*Self-infection* may occur, in addition to the ways mentioned, *by swallowiug the expectoration.* This habit is likely to lead sooner or later to infection of the intestines with tubercular disease.

Knowing the channels of infection, we can easily take effective precautions.

*The sputum must be destroyed, and must not be allowed to become dry.*

A spitting-cup or flask containing just enough disinfectant solution to cover the bottom of the vessel should always be used for the expectoration. Out-of-doors a pocket spitting-flask, such as Dettweiler's, should be employed.

Pieces of linen or calico about ten inches square may also be carried. These should be used only in case of absolute necessity, and should be burnt as soon as possible afterward. No piece should be used more than once.

*Bedrooms* that have been occupied by tubercular patients *should be thoroughly disinfected* before they are occupied by other persons, and a declaration or assurance on the point should always be demanded.

If the previous occupant of the room never allowed the furniture, hangings, or carpets of the room to be contaminated with the sputum, there would be little need for this precaution. But as people, ordinarily of cleanly personal habits, sometimes show a surprising amount of ignorance or carelessness in this respect, the following points should be insisted on:—

1. Carpets, curtains, and bed-coverings should have been exposed to superheated steam under high pressure.

2. The floor and walls of the room should have been properly disinfected. (Rubbing with new bread followed by the application of corrosive sublimate solution is probably the most effective practical method.)

There is *no danger of infection from the breath of a tubercular patient.* The sole danger of social intercourse arises from neglect of the precautions described.

Fresh air is of the highest importance for tubercular persons. Hot and stuffy rooms have an evil influence over the disease. Except in special circumstances, the bedroom window should be kept open by night as well as by day.—*Univ. Med. Journal.*

---

A Magnificent Microscope, costing eight thousand seven hundred and fifty dollars, has been manufactured at Munich for the Chicago exhibition. It possesses a magnifying power of fourteen thousand diameters, and can be increased to sixteen thousand with oil immerson. Electricity furnishes and regulates the source of light, which, placed in the focus of a parabolic aluminium reflector, reaches an intensity of eleven thousand candle power.

# CURRENT LITERATURE REVIEWED.

THE ANNAL OF GYNECOLOGY AND PÆDIATRY FOR JUNE.

Dr. Charles P. Noble contributes two papers; the first.

**Certain Cases of Neglected Pus-tubes.**

He reports three cases of pyosalpinx which were allowed to run their course. The first case died, after years of pain and invalidism, with a huge collection of pus in the abdomen. The second patient had arrived near the period of the menopause without conceiving. The cervix was dilated with the idea of curing the dysmenorrhœa with which she suffered. The result of the operation was a violent attack of peritonitis and pus formation. The abscess finally burst into the bowel and continues to discharge at intervals. Dr. Noble advised the removal of the pus sac. In the remaining cases, the trouble followed the introduction of sponge tents into the uterus for the cure of a catarrh. The patient had an attack of so-called typhoid fever following the treatment, and the abscess finally emptied itself through the vagina. The report is presented to refute the teaching of those who deny the very serious and even fatal character of pyosalpinx when not subjected to early removal by cœliotomy.

The second paper by Dr. Noble is entitled

**Certain Aspects of Puerperal Septicæmia, with the report of a case of Acute Puerperal Cellulitis.**

The author protests against the false position, taken by some, of denying the occurrence of inflammation of the pevic cellular tissue, although he has not met with pelvic cellulitis except in the puerperal state, and as an acute inflammation ending in resolution or abscess. Its occurence is rare, however, as compared with intra-peritoneal inflammation, due to salpingitis or to ovaritis. In the treatment of puerperal sepsis after it has extended to the tubes or to the broad ligaments, the use of the curette or intra-uterine douche is not advisable. We must trust to nature, assisted by our remedies, to bring about resolution, or in case of pus formations must resort to operation. Much depends on whether the secondary inflammation is in the tubes and peritoneum, or in the broad ligament. If in the broad the ligament the pus can be evacuated through the vagina or over the groin. If in the tubes and peritoneum, an early section is imperative.

Dr. Edward P. Davis contributes a paper on

**The Treatment of Large Ovarian Cysts, with the report of a case; Extirpation of the Coccyx for Congenital Cyst.**

In the case of ovarian cyst reported, the patient died of sudden syncope six hours after operation. The total weight of the solid and liquid portions of the tumor reached the great total of 160 pounds. The author raises the question whether it is possible to remove so large a mass from the abdominal cavity without producing such a change in circulation as to cause fatal syncope. Two methods of operating can be practiced; the first is to stitch the cyst to the abdominal walls and use drainage, allowing the cyst to empty itself gradually; the second method is the removal of the entire cyst as practiced.

The second case reported, is an example of abscess over the coccyx without appreciable cause, and accompanied by pain at the sacro coccygeal joint, completely relieved, first by evacuation of the abscess and then by extirpation of the coccyx.

Dr. R. R. Kime discusses

**Ectopic Pregnancy—Pathology, Symptoms and Treatment.**

In regard to the treatment, he says: In primary or secondary intra-peritoneal rupture of the ectopic sac, operate by cœliotomy at once. Before primary rupture, extirpate cyst tube and ovary. Fœticide for this condition by means of electricity and morphia injections, are but temporary expedients, suitable for cases of doubtful diagnosis, or when a competent operator cannot be had. With extra-peritoneal primary rupture into the broad ligament in the early weeks of gestation, producing hematocele, if absorption fail, then perform cœliotomy or vaginal draining. If the child survives primary rupture into the broad ligament, let the fœtus live, keeping the patient under strict observance, ready to operate at any time when the life of the patient demands it or when the fœtus has reached a viable age. Surgical interference should be the rule in all cases of ectopic pregnancy reaching full term, even after spurious labor and the death of the fœtus. After the operation, never give opiates; have the bowels well moved early by salines and enemata; no food, only sips of warm water until the bowels are moved and vomiting ceases. Early catharsis relieves pain, nausea and prevents intestinal obstructions. He has never regretted giving cathartics early after operation, but has seen the evil effects of delay.

Dr. W. Reynolds Wilson contributes a paper on "Uterine Thrombosis Following Post-partum Hemorhage and Its Relation to Puerperal Infection."

In this issue also appears a reprint of Dr. Oliver Wendell Holmes' classic essay on "The Contagiousness of Puerperal Fever," this year being the semi-centennial of its publication.

THE CHICAGO MEDICAL RECORD FOR JUNE

contains a paper by Dr. F. C. Hotz on

**The Importance of Early Mastoid Operations in Acute Suppurative Otitis.**

If the mastoid inflammation is not relieved after a week's trial of antiphlogistic measures (such as blood letting or leeches behind the ear, the douching of the tympanic cavity with warm boric acid solutions, etc.), the author thinks that it may be taken for granted that by this time the mastoid antrum is filled

with pus, and that this pus must be removed if the patient is to get well speedily. Many surgeons perform the mastoid operation on the installment plan, so to speak. Where leeches, warm fomentations and other treatments have failed to give relief, they make a Wilde's incision, and wait a day or two for results; and when they are satisfied that this incision also failed to stay the inflammation, then they proceed to open the cells.

In operating the author prefers the chisel to the drill.

Dr. Charles Warrington Earle contributes a paper on

**The Present Status of the Etiology of Whooping Cough and Its Treatment with Bromoform**

The author is satisfied of the bacterial origin of the disease, and states that with bromoform the paroxysms are diminished very greatly within three days after the commencement of treatment. It should be given in doses of from one-half drop to a child one year of age to two or three drops to children of five or six, suspended to some mucilaginous vehicle. Syrup or water should not be added to the prescription, but glycerine may be used in any quantity without precipitation. Its action is somewhat similar to that of belladonna. The author believes it controls very largely the nervous element in this disease. It has not any germicide properties. It is useful in the second stage, diminishing the number of paroxysms and in this way bringing the disease under control, which, to say the least, excites our solicitation and makes us fearful of complications where the paroxysms are from twenty to thirty each day. Previous to the time that his attention was called to bromoform, the author had relied almost entirely upon fumigations, using tincture of iodine and carbolic acid. With the bromoform to combat the neurotic tendency and the fumigations of carbolic acid and tincture of iodine to destroy the micro-organisms, we have a treatment which promises more than any other combination of remedies. It is quite probable that the action of bromoform and belladona may be somewhat similar, but as between the two remedies the bromoform has given the better results.

Dr. C. S. C. Plummer contributes a paper on

**Punctured Wounds of the Feet,**

being a report of two hundred and three cases treated at the Medical Bureau, World's Columbian Exposition, during the "Construction Period," June 1st, 1891, to May 1st, 1893.

Although treatment varied much in different cases, the routine treatment finally agreed upon as being applicable to most cases and followed by the best results, was as follows:

1. Thorough cleansing of the foot with solution of bichloride of mercury 1-1,000.
2. Trimming the edges of the wound.
3. Swabbing out the wound with a probe lightly covered with cotton and dipped in 95 per cent. solution of carbolic acid.
4. Drainage.
5. Antiseptic dressing.
6. Rest.

Other papers in this month's issue are: "The Treatment of Typhoid Intestinal Hemorrhages" by Dr. A. A. Knapp, in which the author advocates the administration of a hyperdermic injection of a quarter grain of sulphate of morphia, followed by powdered opium in one grain doses every hour while awake, unless the respirations fall below twelve per minute. The paper includes a report of cases in which the treatment was used. Dr. A. E. Hoadley presents a paper on "The Importance of Early Mechanical Treatment of Hip Joint Disease." The issue concludes with a letter from Dr. Keeley in which he denies the truth of the statements of Dr. Chauncey F. Chapman in his paper on "The Bichloride of Gold Treatment of Dipsomania" (a notice of which was published in THE MEDICAL AND SURGICAL REPORTER for March 25th, 1893), and the reply of Dr. Chapman, in which he affirms that his statements are, in the main, true.

# PERISCOPE.

## THERAPEUTICS.

### Heat and Chloroform.

Decomposition of chloroform by the presence of light and heat from an open fire, not infreqently occurs and is disagreeable to operator, assistants, attendants and patient. Little has been known about the matter until the *Medical Press and Circular* in a recent issue called attention to the danger. In December last, in this city, during an operation for hemorrhoids, chloroform being the anæsthetic employed, the operator, anæsthetizer and attendant began to cough violently; this was accompanied with irritation and watering of the eyes and dry and irritated throat, and a strong and pungent odor of free chlorine was noticed. The cough and discomfort in eyes and throat continued for a considerable time after leaving the operating room. It was supposed that the chloform was impure, and the bottle with what remained of its contents was sent to the manufacturer, Dr. Squibb, of Brooklyn, who reported, after analysis, that it was entirely pure. It was then remembered, that, as it was a cold day, an oil heating stove had been burning during the operation. This fact Dr. Squibb considered as the cause of the decomposition of the chloroform with evolution of free chlorine. The patient in this case suffered no discomfort whatever.—*Medical Review.*

### Creolin a Mixture of Crude Carbolic Acid and Resin Soap.

From a trade circular issued by Dr. F. Raschig, a competent chemist and manufacturer, we learn that,

"Creolin is nothing more than a mixture of about 2 parts crude 20 per cent. carbolic acid and 1 part resin soap, and consequently contains about 10 to 15 per cent. of crude carbolic acid—to which solely it owes its disinfectant power."

This positive and trustworthy statement is made to counter the specious claim by the creolin manufacturers that their product is "made from coal-tar creasote free from all carbolic acid." Dr. Raschig lends emphasis to the exposure by pointing out that "coal-tar creasote and 20 per cent. crude carbolic acid are identical"—thus "hoisting by their own petards" his opponents in the argument.

Creolin has done good service, but is now excelled by lysol.—*Notes on New Remedies.*

### Prentiss (D. Webster) on the Effect of Pilocarpine in Changing the Color of the Hair.

Having used pilocarpine with great success in a case of uræmia, Dr. Prentiss was much interested to note its effect on the patient's hair. The drug was administered by the hypodermic method in doses of one centigramme, and the total amount injected (in two or three days) was forty centigrammes. The hair, which previous to this time had been light brown, began rapidly to change its color to dark brown, and later became black. It also became coarser and thicker. These changes occurred not only in the hair of the head, but also in that of other parts of the body. The author states that two cases of a similar effect—though less marked—have been recorded, and speaks of the occasionally marked effect of pilocarpine in promoting the growth of hair.—*Med. Rec.*, April 15, 1893.

## MEDICINE.

### The Treatment of Malaria by Means of Potassium or Sodium Nitrate.

Dr. Peter Buro in "Deutshe Med. Zeitung," having experimented with the above salts in the treatment of malaria, reports the following:

1. The nitrate of potassium and the nitrate of sodium are specific remedies in typical malarial intermittent, whether it assumes the quotidian, tertian or quartan form.
2. Both salts manifest an exact action but the sodium salt has the advantage of being free from the slightly toxic effect of potassium.
3. The usual single dose for adults is from 15 to 24 grains, which may be given in either the febrile or afebrile stage.
4. A decided advantage of these salts is that they exert no ill effect upon the digestive organs or nervous system, nor do they produce any untoward results.

### Tincture of Iron for Burns.

Dr. E. F. Starr, in the *Atlanta M. and S. Journal*, recommends the application of the tincture of chloride of iron, by means of a feather or soft brush, as a prompt and efficient remedy for recent burns. The application should be made as early as possible, and should be done thoroughly, moistening it everywhere. Where the cuticle is not destroyed or removed, it should be used full strength; if the cuticle is gone, dilute with water one-half or two-thirds.

If used early in scalds and superficial burns it not only allays the pain but prevents blistering.

### The Iodine Treatment of Goitre.

*Dr. E. Nazaries, Bulletin de la Societe de pharmacie de Bordeaux*, Feb., 1893; *American Journal of Pharmacy*, May 1893), remarks that, while iodine has long been used in the treatment of goitre, he has met with unqualified success by a particular method of its use. He dissolves from 75 to 90 grains potassium iodine, and from 20 to 30 drops of tincture of iodine in about 5 ounces of distilled water. A spoonful (whether teaspoonful or tablespoonful, not stated) of this solution is diluted with a pint of water, and this amount taken daily, during and after meals. The author insists on the continued internal use of the drug.—*N. Y. Med. Jour.*

### Diagnosis of Apoplexy.

Mills (*Polyclinic*) based the diagnosis of apoplexy on the following points:

1. The sudden fall with unconsciousness at once, no injury perceptible, face white.
2. Respirations stertorous, noisy, puffing cheeks, tendency to Cheyne-Stokes, interrupted, improved by turning on side.
3. Right face droops more, and right cheek flaps more than the left. Right pupil widely dilated; left contracted. Retinal veins distended. No rotation of head and eyes to one side.
4. Pulse full and slow; temperature subnormal.
5. Convulsive movements noted at first have ceased; both arms and legs drop lifeless equally. Left side was paralized first. Sensation almost completely abolished.

## SURGERY.

### The Surgical Treatment of Cholera.

Five cases have up to the present time been published in which cholera was treated surgically. M. Lambotte operated upon two patients last autumn. The abdomen was opened in the middle line, and the bowel sown to the wound, incised and flushed out with a solution of corrosive sublinate (1 in 3000) by means of an india rubber tube one metre long. Both patients died. A Russian physician, M. Meerovitch, of Ekaterinodar, operated upon three patients last August

Only a small puncture was made into the bowel, which was not stitched to the wound. From 2000 to 3000 grammes of a solution of tannic acid were injected in two of the cases and 4000 grammes of a solution of thymol in the third. In all three cases there was a fleeting improvement in the symptoms, but all the patients died.—*Bost. M. & S. Jour.*

### Tropical Suppurative Hepatitis.

Surgeon Patrick Hehir, of the British Indian Service, formulates, in the *Indian Medical Gazette*, the following pathalogical classification of cases of hepatic abscess:

(1) By far the most common are cases occurring consecutive to dysentary, and arising from a secondary infective process affecting the liver through the portal circulation. These cases arise from:

(*a*) The action of septic organisms, such as the streptococci, staphylococci, micrococci; or

(*b*) The irritation of the products of such septic organisms—ptomaines, conveyed to the liver from the ulcerated bowels and acting primarily on the liver, which plays the part of a filter upon the blood conveyed to it by the portal vein, or to the irritation of the amœba coli or cercomonas intestinalis, or both combined. Cases due to malarial poisoning, the blocking up of the radicles of the portal vein by the plasmodia of Laveran, these organisms acting as irritants and lighting up the suppurative process.

(2) Acute sthenic parenchymatous inflammation resulting from climatic causes, overcrowding, alcoholic excesses, excessive heat or chill, acting upon a liver already in a partial state of disorganization.

(3) Idiopathic cases in which no assignable cause can be traced.

### Intestinal Anastomosis.

Murphy describes an "anastomosis buttom."

It consists of two small circular bowls made of bone. In one bowl is fitted a small cylinder with a female screw-thread on its entire inner surface. In the other bowl is fitted a smaller cylinder, of a size to slip easily into the female cylinder. On the inner surface of the lower end of the male cylinder two small brass springs are fixed, which serve to hold the bowls together when the male cylinder is pressed into the female cylinder. In the side of each bowl are four openings which serve for drainage. The whole button has the form of two hemispherical bodies held together by invaginating cylinders. These hemispheres of the button are inserted in slits or ends of the viscera to be operated upon. A running thread is placed around the slits in the viscus, so that when it is tied it will draw the cut edges within the clasp of the bowl. A similar running thread is applied to the slit in the viscus into which the other half of the button is inserted, and the bowls are then pressed together. The pressure-atrophy at the edge of the bowl is produced by a brass ring supported by the spring. The opening left after the button has liberated itself is the size of the button. For this device the inventor claims the following advantages: (1) It retains its position automatically; (2) it is independent of sutures; (3) it produces a pressure-atrophy and adhesion of surfaces at the line of atrophy; (4) it ensures a perfect apposition of surfaces without the danger of the displacement; (5) it is applicable to the lateral as well as to the end-to-end approximation; (6) it produces a linear cicatrix, and thus ensures a minimum of contraction; and (7) it it extremely simple in its technique.

Three cases of cholecysto-enterstomy with this device are reported with apparent good results, In one case the time occupied by the operation was eleven minutes. Other experimental operations on animals are reported as having been done successfully. These include cholecystic-enterostomy, gastro-intestinal anastomosis and entero-intestinal anastomosis.—*Bost. Med. and Surg. Jour.*

### Bloodless Amputation at the Hip joint.

Dr. Senn has described a new method, devised by him, for the bloodless amputation of the hip-joint (*Chicago Clinical Review*). The following conclusions are presented by the author, as embodying the advantages of this operation: 1. Preliminary dislocation of the head of the femur and clearing the shaft of this bone of all soft tissues down to the proposed line of amputation through an external straight incision requires less time, is attended by less hemorrhage and shock than when this part of the operation is done after circular amputation, as advised by von Esmarch and others. 2. The external straight incision is the same as the von Langenbeck incision for resection of the hip-joint, differing only in length. 3. After dislocation of the femur the soft tissues are tunnelled with a hæmostatic forceps which is entered through the external wound on a level with the trochanter minor to a point on the inner aspect of the thigh behind the adductor muscles and about two inches below the ramus of the ischium, where a counter-opening two inches in length is made. 4. Bloodless condition of the limb should be secured by elastic compression or vertical position prior to tying the elastic constrictors. 5. An elastic tube three-quarters of an inch in diameter and about four feet in length is grasped with the force in the center and drawn through the tunnel made by the forceps. 6. After dividing the elastic tube in the centre the base of the thigh is constricted by drawing firmly and tying the anterior constrictor in front of the anterior section, while the posterior constrictor after being drawn tight behind the posterior section the two ends are crossed and then made to encircle the whole thigh, when the ends are again drawn firm and tied or otherwise secured above the anterior constrictor. 7. A long and short oval cutaneous flap should invariably be made in all amputations at the hip-joint. 8. In perference a long anterior and a short posterior flap should be selected. 9. The transverse section through the muscles should be some what conical in shape,

the apex of the cone corresponding to the tunnel made by enucleation of the upper portion of the shaft of the femur. 10. Resection of the end of the sciatic nerve and ligation of all vessels that can be found should be done before the removal of the constrictors.

The femoral arteries should be secured by a double catgut ligature spread half an inch apart, the one portion on the proximal side including also the accompanying vein. The posterior constrictor should be removed first, and all hemorrhage arrested by ligation and compression before the anterior constrictor is removed. 13. The upper part of the wound corresponding to the acetabulum should be drained with an iodoform gauze tampon, and the remaining part of the wound by one or more tubular drains.—*Med. Record.*

## OBSTETRICS.

### Conception on the Fourth Day of Childbed.

Kronig (*Centralbl. f. Gynak.*, No. 19, 1893), related an extraordinary and instructive case at a meeting of the Leipzig Obstetrical Society. A woman, now twenty-two, healthy and regular before her pregnancies, bore her first child on July 4, 1892. It was weaned on the tenth day, and is still living. On July 8, the fourth day of the puerperium, the patient had connection and then abstained for three months from coitus. The period did not return. In November, 1892, the motion of the child was felt. It was born on March 10. It seemed as though it had reached term, yet it had come into the world 243 days after the only connection which had occurred since the first confinement, or twenty-seven days—practically a calendar month—before the normal average of 270. It was over twenty inches long and weighed nearly seven pounds twelve ounces.

The shortness of the pregnancy was very remarkable, but the conception on the fourth day of the puerperium was still more notable. Ovulation, according to current theories, is entirely suspended during pregnancy, and does not recommence until, or a little before the first period, which occurs between the sixth and eighth week after delivery in women who do not suckle. If ovulation was delayed so long in this case, the spermatozoa must live long; Bozzi certainly found them living seventeen days after coitus, in the posterior vaginal fornix: but in Kronig's case this delay of conception to the first period would have made the pregnancy much too short to allow of the birth of a well-formed child.

In short, ovulation went on quite independently of menstruation. How the impregnated follicle could find a fit place of attachment on the inner surface of the uterus is a more mysterious question. Yet the glandular structures developed during pregnancies are often completely shed by the third or fourth day after childbirth, so that there is soon enough normal endometrium to lodge a fresh ovum. It is evident that spermatozoa can live in the lochia.—*British Med. Journal.*

### A Valuable World's Fair Book.

The Passenger Department of the Baltimore and Ohio Railroad Company has prepared for general distribution a handsome pamphlet descriptive of the scenic and other attractive features of that road from New York to Chicago. This book should prove invaluable to those visiting the World's Fair. In its artistic cover, illustrations and reading matter, it is fully up to the high standard which has been fixed by the B. & O. for publications of this character. The scenery en route, which has gained for the B. & O. the richly deserved sobriquet of "Picturesque," the public buildings at Washington, old Harper's Ferry, Luray Cavern, and other attractive points are faithfully portrayed. The value of the publication is increased by descriptions and illustrations of the principal buildings at the World's Fair. This book can be procured free of charge upon personal application to ticket agents, B. & O. R. R. Co., or you can have it mailed to you by sending name and address with five cents in stamps to Chas. O. Scull, General Passenger Agent, Baltimore, Md. World's Fair tourists should bear in mind that the B. & O. is selling tickets at very low rates good going via Washington and returning via Niagara Falls.

### Deer Park and Oakland.

To those contemplating a trip to the mountains in search of health and pleasure, Deer Park, on the crest of the Allegheny Mountains, 3,000 feet above the sea level, offers such varied attractions as a delightful atmosphere during both day and night, pure water, smooth, winding roads through the mountains and valleys, and the most picturesque scenery in the Allegheny range. The hotel is equipped with adjuncts conducive to the entertainment, pleasure and comfort of its guests.

The surrounding grounds, as well as the hotel, are lighted with electricity. Six miles distant on the same mountain summit is Oakland, the twin resort of Deer Park, and equally as well equipped for the entertainment and accommodation of its guests. Both hotels are upon the main line of the Baltimore and Ohio Railroad, have the advantages of its splendid Vestibuled Limited Express trains between the East and West and are most desirable resting places for World's Fair tourists. Season Excursion tickets, good for return passage until October 31st, will be placed on sale at greatly reduction rates at all principal tickets officers thoroughout the country. One way tickets reading from St. Louis Louisville, Cincinnati, Columbus, Chicago, and any point on B. & O. system to Washington Baltimore, Philadelphia, or New York, or vice versa, are good to stop off at either Deer Park or Oakland, and the time limit will be extended by agents at either resort upon application.

The season at these popular resorts commences June 15th.

For full information as to hotel rates, rooms, etc., address George D. DeShields, Manager, Deer Park, or Oakland, Garrett County, Maryland.

# SVAPNIA

OR

## PURIFIED OPIUM

**FOR PHYSICIANS USE ONLY.**

**Contains the Anodyne and Soporific Alkaloids, Codeia, Narceia and Morphia.**

**Excludes the Poisonous and Convulsive Alkaloids, Thebaine, Narcotine and Papaverine.**

SVAPNIA has been in steadily increasing use for over twenty years, and whenever used has given great satisfaction.

To PHYSICIANS OF REPUTE, not already acquainted with its merits, samples will be mailed on application.

SVAPNIA is made to conform to a uniform standard of Opium of Ten per cent. Morphia strength.

JOHN FARR, Manufacturing Chemist, New York.

**C. N. CRITTENTON, Gen'l Agent, 115 Fulton St., N. Y**

**To whom all orders for samples must be addressed.**

**SVAPNIA IS FOR SALE BY DRUGGISTS GENERALLY.**

---

**NO WAX**

Is used in our **Hollow Suppositories.** Made from purest **Butter of Cocoa only,** which **melts** at the temperature of the **body.** Can be filled with any medicine. Anal, Nasal, Urethral, Cystic, Vaginal, and Intra-Uterine sizes.

Also, Ricord's Solid Suppositories for Gonorrhœa, and Nelaton's Solid Suppositories for Constipation and Piles. Samples sent Free on application and mention of this paper.

HALL & RUCKEL,

218 Greenwich St. New York City.

---

**MARLIN SAFETY**

**REPEATING RIFLES**

Made in all styles and sizes. Lightest, strongest, easiest working, safest, simplest, most accurate, most compact, and most modern. For sale by all dealers in arms. Catalogues mailed free by

**The Marlin Fire Arms Co.,**

NEW HAVEN, CONN., U. S. A.

## ORIGINAL ARTICLES.

### DIPHTHERIA*

T. J. HAPPEL,† A.M., M. D.

I venture to call attention to this malady not so much with a view of throwing new lights upon an old subject as for the purpose of eliciting a discussion and a comparison of views entertained in regard to the disease as it manifests itself in Tennessee.

In different parts of the State during the year 1892 the existence of diphtheria was reported. The county of Gibson did not escape. But one case occurred in my own practice, but I was called in consultation to see cases treated by three other practitioners near Trenton; the cases being distant respectively five, six, and ten miles from Trenton. I submit a brief history of these cases and then draw my conclusions.

Sept. 2, 1892, I was called in consultation to see the three children of Mr. V. The family lived on an elevated point, within 200 yards of an old saw-mill which had been abandoned for eight or ten years. The sawdust that had accumulated at that point lay rotting year after year, affording a nice playing place for children, and was no doubt so utilized by them. Otherwise the place presented as good sanitary surroundings as are usually found about country farmhouses. I found the children aged 11, 6 and 4 years. The oldest attended a neighborhood school, and four days since, though a little unwell, was at her place as usual, but came home that evening sick, having high fever.

During the night Dr. M. was called, but did not see the case until the next day, the family supposing the attack an ordinary chill. Dr. M. at this visit regarded the attack as malarial fever with catarrhal symptoms, accompanied by a slight tonsillitis. The next day he found the second child also sick, and the symptoms calling attention more to the throat, he found tonsillitis with extensive exudation in both cases. The next day the exudation assumed the form of pseudo-membrane and extended posteriorly and laterally over the fauces, and anteriorly along the soft palate in the first case, but not so extensively in the second. The temperature and pulse had both decreased in the first case, falling slightly below normal, and in the younger the temperature was normal. I was called on the fifth day of the disease in the oldest child, being the third day in the second.

An examination of the throat of the oldest revealed pseudo-membrane on both tonsils, not quite meeting in the median line posteriorly, and the one on the left side extending anteriorly along the hard palate fully two inches, loosening along the anterior edges, and appearing to be about one and a half lines in thickness.

Case 2 showed patches of false membrane about the size of a nickel on each tonsil, extending downward and toward

* Read before the Tennessee State Medical Society, 1893.

† Ex-President Tennessee State Medical Society; President Western Tennessee Medical and Surgical Association.

the middle. This child claimed not to be sick, wanted to play about, with a pulse of 120 and a feeble, anæmic look. Face pinched and white. The same could be said as to the appearance of the oldest child, but she admitted that she was sick, and was willing to lie in bed, being easily exhausted by any exertion.

The youngest child was a little hoarse, with slight fever, but was able to play about. His throat revealed no patches, only a redness and slightly enlarged condition of both tonsils. Under a mopping of the throat of the eldest girl (having first used a wash of peroxide of hydrogen full strength, and then following with a solution of papoid), in an effort of coughing, the whole of the large part of this membrane attached anteriorly to the hard palate was detached and coughed out,leaving a raw and, in a few points, bleeding base.

In the other child's throat nothing was detached under the same treatment, though very decided action resulted when the peroxide was brought in contact with the false membrane. Both children were much tired by the application. These children had been treated up to that time with quinine, and aconite and gelsemium when temperature was above normal, and the throats had been mopped with listerine alternated with a saturated solution of chlorate of potash, which latter remedy had also been administered internally. Neither child had any desire for food, and none had been forced on them.

It was agreed first that all clothes, mops, etc., used about the throat, or upon which any of the secretions from the throat were received, should at once be burned. That in the absence of an atomizer, applications should be made to the throat by means of soft mops made of absorbent cotton. Second, that the disease should be treated locally with applications of peroxide of hydrogen (Marchands) followed at once by a solution of papoid. Third, that as internal remedies, alcohol in different forms should be given as demanded by each case. Fowler's solution of arsenic was ordered every four hours. Fourth, the youngest child was ordered sent to a relative, who had no children, with directions to mop the throat with a solution of persulphate of iron and chlorate of potash, and given full doses of quinine three times a day. Fifth, all children were ordered to be kept away from contact with the cases.

Sept. 4th. The appearance of the throats of both the children had improved, except that the membrane, much thinner and smaller every way, had been reproduced over the portion of the palate of the oldest child from which it had been removed. Temperature subnormal in this case with a slow feeble pulse, complete anorexia, and decided aphonia ; very weak. The second child was better in every way.

Sept. 6th. Throats of both cases improved so far as pseudo-membrane was concerned. Pulse and temperature in the oldest child subnormal. Deglutition difficult with a tendency on the part of drink and food to return through the nose, prostration great, with a loathing of food. It was decided to add to her treatment a pill of iron, quinine, and nux-vomica, with phosphorus, and to press alcholic stimulants. Prognosis in this case very grave. The second child improved in every respect. No delopment of disease in the third.

Two days later, gangrenous symptoms supervened in the first case, and two days later sloughing began. The child died suddenly from heart failure on the fifth day after my last visit. The other child slowly recoverd. The third child did not develop the disease.

On Sept. 6th, I was called in consultation with Dr. M. to see a two year old child of Mr. T., who also lived not far from an old saw mill. A few days before, the little boy was found with fever, a sore throat and developing croupy cough. Dr. M. reported that when he called he found a slight tonsilitis, with pharyngitis, also a laryngeal cough. At that visit he found no membranes. At his next visit the symtoms were the same but membranes could be plainly seen. I was called the next day. I found the child playing on the floor. There was a stridulous cough and a shrill respiration which could be heard outside of the room. Temperature and pulse almost normal. I discovered membranous patches on both tonsils. There were no other children in the family.

The treatment locally consisted of a spray of peroxide of hydrogen followed, as in the first case, with a solution of papoid. Dr. M. had been using sulphur by insufflation. This was continued.

Quinine 2 to 3 grs. every 4 hours, to be alternated at the same intervals with mercuric bichloride gr. $\frac{1}{48}$. Egg-nogg, milk punch and toddy were directed to be freely used. At the third visit, tr. ferri mur. was added to the foregoing treatment. The spraying was kept up regularly till every trace of the membranes had disappeared. The bichloride was not suspended till, in addition to the disappearance of the membranes, the laryngitis had subsided. Dr. M. had just prior to this one lost two patients in the same neighborhood.

Nov. 6th, saw, in consultation with Dr. K., Miss B., aged 11 years, presenting a well developed case of diphtheria with slight laryngeal symtoms. She, too, lived not far from an old saw mill. Temperature for a few days was high, but had fallen to about normal; pulse frequent, feeble, and irregular; prostration decided. Her treatment consisted of the same spraying and mopping, alcoholics and nutrition, with scrupulous regard for cleanliness, and Tr. Ferri Mur. gtt. 4 every four hours with ℞ : Hydrarg. Bichlor. grs. 1, Liq. Arsenici Chlor. drams 1, Acid Muriate, dil. drams 2, Glycerinæ, drams 3, Aquæ q. s. oz. 4, M.et ft. mist. Sig.: Teaspoonful every four hours; alternate with the iron.

From the adoption of this treatment her improvement was steady but slow. At the end of two weeks all traces of the disease except extreme debility had disappeared.

My own case, occurring in Trenton, was milder than any of those reported and recovered on about the same treatment, except that the throat was treated with a solution of persulphate of iron and chlorate of potash.

During the prevalance of this disease, a number of cases of diphtheritic croup attached children under two years of age. Tracheotomy was performed in at least four (4) of these cases with fatal results in all. The cases not operated on as a rule died also.

I have thus briefly reported these cases to invite your attention to some thoughts upon the disease and more especially upon its treatment.

According to the latest writers upon the subject, diphtheria is due to a specific germ, the Klebs-Loeffler bacillus. This statement is made on the ground that in cases of diphtheria the pseudo-membrane is found inhabited by vast colonies of this bacillus. Yet our same bacteriologists admit that membranes are found in many cases which cannot be distinguished by appearance or anatomical characters from that of true diphtheria except by the absence of the Klebs-Læffler bacillus; ergo, no case of diphtheria can be positively diagnosticated without the aid of a microscope. Again, in *L'Union Medicale*, Nov. 14th, 1892, Roux and Versin state that in fifty healthy children examined in Paris and elsewhere in France, they found in the mouths of twenty-six of these children "a bacillus which, in a morphological point of view, is identical with the Klebs-Lœffler bacillus." The difference which they could discover was not in its individual form nor in the form of its colony, but only in the numbers of its colonies. This being true, does it not at once raise the question, or rather establish as a fact, what is stated by them to be a belief "that this harmless bacillus is none other than the Klebs-Lœffler bacillus deprived of its virulence?"

A search for this bacillus might reveal its presence much more common, and might carry the etiology of the disease to this point. "This Klebs-Lœffler bacillus exists in the secretions of the buccal surfaces of many persons, and when brought in contact with a *tertium quid*, causes the secretion by these bacilli of a tox-albumen which is absorbed, resulting *first*, in the manifestation of local disease and, *afterward*, a blood-poisoning resulting in constitutional symptoms." I simply suggest this as the probable etiology of the disease. The facts are as stated. These bacilli are found in the mouths of healthy persons. They are also found in pseudo-membranes which are not considered diphtheritic simply because when the bacilli are secured from that source and cultivated, or innoculated, they neither develop large colonies nor produce local trouble; and yet the microscope cannot differentiate these bacilli from those found in the most malignant cases of diphtheria. If this be a solution of the question, I can account for the development of the cases appearing in Gibson County during the past year upon the supposition that in nearly every case the rapid decay of the old saw-dust, which was near every neighborhood in which any case de-

veloped, furnished the pabulum on which the bacilli grew and multiplied.

In connection with the Klebs-Lœffler bacilli, the microscope, according to Roux and Versin, shows also staphylococci and streptococci pyogenes in the meshes of the membrane. The bacilli either live in, or cause the production of the pus, which is found intermixed in the pseudo-membranes. For these we will have use later on in the treatment.

It has been further proved by Klebs-Lœffler, Roux and others that if cultures of these bacilli are filtered through a porcelain filter no bacilli are found in the filtrate, and that this filtrate solution injected causes no local manifestation of diphtheria but develops the constitutional disturbances seen so often in the disease. If the solution is strong or considerable in quantity, death rapidly supervenes, but if less in degree, the animal "lives longer but suffers from paralysis;" hence, the statement already made that these bacilli generate a tox-albumin as they grow, which gives rise to the constitutional symptoms. So much for the etiology of the disease.

*Prognosis.* The statistics of the mortality differ widely. The reports from many of the best hospitals give the rate at from 31 per cent. to 47 per cent., but widely different are the reports in private practice. Dr. John M. Boyd, of Knoxville, Tenn., in 1888, at the Tennessee State Medical Society, read an article on diphtheria and veratrum viride, as the basis of treatment, in which he used the following language: "In the six years since, sixty-seven cases have fallen principally to my care, and a number of others, in which I have had a consultant relation, and under its (veratrum's) timely use, its claims to the merits of extraordinary efficiency have never disappointed me." One practitioner in Washington City claims in private practice, fifteen successive cases without a death. (*Va. Med. Monthly*, Feb. 1893, page 908.) Osler holds that in hospital practice the disease is very fatal but that in private practice, except in very malignant epidemics, the prognosis is very good.

My own experience with the disease, whilst limited, is not favorable. Almost without exception the cases of diphtheritic croup where the presence of membrane was fully proven, were fatal. I admit that one or two recovered out of twelve or fifteen cases seen and reported, but no membrane could be demonstrated except in one case.

In a discussion of the question of membraneous croup, which took place in the Gibson County Medical Society this year (1893), the members speaking to the question and taking the position that membraneous croup and diphtheria were identical, reported a number of cases which had come under observation. One member reported seventeen cases of diphtheritic croup met with in a series of years, all fatal; another, five cases with four deaths; another, five cases in which tracheotomy had been performed, all fatal; another did not give the number of cases but reported all fatal. The mortality was at least twenty per cent of those cases seen by, and reported to me in the fall of 1882.

This wide difference of results can be accounted for only upon the supposition that many cases are diagnosed diphtheria which are only cases of tonsilitis, or of pharyngistis with an exudate not a false membrane. These exudates *sometimes* so closely resemble the diphtheritic membrane that the eye cannot distinguish them, yet the microscope promptly shows the difference, while the simple test of agitating them in warm water would give strong proof for or against the disease;—the exudate generally readily dissolving, or at least separating into small fragments, whilst the diphtheritic membrane will not. Of course, the "whiping off" test with soft absorbent cotton will aid very materially in making a diagnosis

Treatment.—This should be local and constitutional, in accordance with the modern ideas of the disease. Remedies for local application have been almost as numerous as are pharmaceutical preparations. Without attempting to discuss the merits or demerits of the large majority I would simply call attention to those that I have found useful. In the first place I put peroxide of hydrogen. The fact that we find in these pseudo-membranes streptococci pyogenes—the pus generating cocci—and that pus is held in the meshes of this membrane, and the further fact that has been proven beyond cavil, that it hunts out, combines with and decomposes these pus globules proving at the same time a germicide of the highest type,

Hydrogen Peroxide becomes then the application *par excellence* in these cases. This I use if I can, first with a soft mop made of absorbent cotton, and then, in order that I may not fail to reach membranes hidden from sight, I follow by a spray of the same through the anterior nares and mouth. In young children, I use the spray alone to avoid so much worry. I use the reagent undiluted unless I find it irritating; then I dilute as little as possible.

After a few moments rest, with another mop I saturate the membranes wherever visible, with a solution of papoid, (vegetable pepsin) nine grains to the drachm. This, in my hands has proven a powerful solvent of these membranes. These applications are repeated in bad cases every two hours, in milder ones every four hours.

I cannot say that I have gotten any benefit from solutions of iron or chlorate of potash locally in these cases, though I frequently use the potash solution as a gargle with children old enough to use it. In some of my cases I caused sulphur to to be blown into the throat to satisfy a popular prejudice, at the same time hoping that it might be converted into sulphurous acid and act as a germicide or by attrition at least aid in wearing off the membrane. Externally I make stimulating applications to the throat.

Recognizing that this disease rapidly becomes constitutional I open up the alimentary canal with a mercural purge and then direct that the secretions of bowels, kidneys and skin be carefully watched and kept normally active.

The high temperature of the first twenty-four or forty-eight hours demands antifebrine or some other of the phenol group of antipyretics, repeated as often as needed to hold the temperature down to or below 100.° Generally there are several days when heart sedatives may not be needed at all, but as the disease progresses it will become necessary to tone and reduce the frequency of the heart's action. This can best be done with digitalis and aconite combined, in small doses often repeated. Later on the aconite must be omitted, the digitalis kept up supplemented by alcoholics freely administered. Alcohol in some form becomes a most valuable adjuvant in the treatment of diphtheria.

As to constitutional remedies, bichloride of mercury stands first and should be given in full doses every four hours. For a child two years old, I do not hesitate to order one forty-eighth of a grain every four hours, but I should hesitate with so young a child, to go to the extent suggested by Osler, viz: one-half a grain in all, each day. Next in utility is tr. ferri. chlor. in doses of four to ten drops every four hours, for a child two years old, and two grains of quinine at the same time.

Third in value is placed liq. potasii arsenitis, or chloride of arsenic. Favorite prescriptions of mine are

℞ Hydrarg bichlor..... 1 grain
Alcohol..... q.d. ft. sol
Liq. arsenici chlor ..... 1½ drachms
Acid, muriatici dil ..... 2 drachms
Potassii chloratis ..... 3 drachms
Aquae ..... q.s., 4 ounces
M. et ft sol.
Sig.—Teaspoonful in water every four hours.

Alternate with tr. ferri mur. in doses already stated every four hours.

I do not propose to refer to all other remedies used, but these have been found valuable in my hands. If, in the course of the disease, diphtheritic croup develops, then an atmosphere charged with the vapor of turpentine and eucalyptol is to be abundantly supplied to the patient, either by surcharging the air of the room by means of a vessel of boiling water containing these medicines (such can easily be arranged with a gasoline stove or large alcohol lamp) or the vapor may be conducted close to the child's face by wetting cloths in the mixture and hanging around the bed. In such cases an emetic will often be needed to dislodge the mucus from the trachea and bronchi. Ipecac in the form of the fluid extract has given me most satisfaction. I generally use it combined with belladonna. Belladonna is strongly indicated in these cases when the blood is not properly aerated.

The question of intubation or tracheotomy presents itself in most of these cases. From the failures in tracheotomy cases I would favor intubation. But it is not the province of an article of this kind to discuss the relative merits of either.

Whatever treatment is adopted, the result depends largely on the nature of the case, whether sporadic or epidemic, whether simple, mild, or malignant. If the etiology assumed is correct, the treatment suggested ought to prove curative. It has done good in my hands; hence I present it.

Sequelæ must be met as they arise, although it is better to prevent them by closely watching the case and resorting in time to proper remedies. For example: The timely use of strychnia, hypodermically or *per orem*, may prevent paralysis. Should it develop, no time has been lost and we are prepared to continue our treatment more regularly.

I have not entered upon the question of prophylaxis, because, in this enlightened age, no one can or will deny the absolute necessity for the adoption of the most thorough and careful preventative measures.

In conclusion, it must not be forgotten that we are dealing with a disease of which the virus or germ, or whatever the source of infection may be, is most tenacious of vitality, and hence, in all cases, everything used around a case of diphtheria should be thoroughly disinfected by heat dry or moist, fumigation with sulphur, washing with bichloride solutions, etc. These measures should include rooms, beds, bedding, clothing, etc. Cases have been reported of diphtheria developing in families which have moved into houses that, weeks or months before, had contained a case of diphtheria.

---

## FUTHER OBSERVATIONS OF THE RELATION OF PELVIC DISEASE AND PSYCHICAL DISTURBANCES IN WOMEN.

GEORGE H. RHOE, M. D., Catonsville, Md.

At the last annual meeting of this association, it was my privilege to report eighteen cases of removal of the uterine appendages in insane women, with the results following the operation. In supplementing my previous report with this brief paper, I desire to touch upon a feature of the question which has arisen in the interval; namely, the medico-legal relations of this work.

Of the eighteen cases reported last year, three had been discharged recovered at the date of the report. These cases up to the time of this writing, remain well and continue doing their daily household work. One other has been at home for seven months, not entirely well, but so much improved that she can be cared for outside of an insane hospital.

Another case (of seven years' residence in the hospital) has so much improved in disposition since the cessation of the periodical menstrual irritation that I look forward to discharging her from the hospital also.

Since last September I have operated on two additional cases, one of periodical maniacal violence, and the other of melancholia with loud complaints of intense headache. In both cases the ovaries were cystic. The former case has had no outbreak since the operation, but is still detained for observation, while the latter has been discharged entirely recovered, a recovery dating from convalescence from the operation.

The simple results of this work are therefore as follows:

Twenty operations (removal of the uterine appendages) upon insane women with pelvic disease. Eighteen physical recoveries from the operation, with improvement of the general health. Two deaths.

Four absolute mental recoveries and discharge of patients from hospital restraint. (2 thirteen months, 1 ten months, 1 two months).

Three with complete physical and partial mental recovery. (1 at home seven months.)

Seven show mental improvement, some of them of a very decided character, but none sufficient to justify discharge from the hospital.

Three remain in about the same mental condition as before the operation but are much improved physically.

One was removed from the hospital a few weeks after the operation against my advice, and then placed in an Asylum, where I am informed she has been growing worse mentally.

I may also refer here to a case of melancholia with suicidal tendencies, in which I repaired a badly lacerated cervix. The operation was followed by rapid restoration of the mental faculties and the patient

was discharged recovered on January 31, 1893. She remains well at the date of writing.

At the time when I began this work I was simple-minded enough to think that the restoration of an insane woman's mind was an object desirable in itself, even if it involved the loss of organs so unessential to physical life as the ovaries and fallopain tubes, and especially when these were in a state of disease. It seems however that certain influential members of the medical and legal professions regarded this as a grave and dangerous error and believed it a public duty to endeavor to check similar work which had been begun with encouraging success in one of the insane hospitals of Pennsylvania. The objections urged were based upon misconceptions of the scope and character of the work. The weightiest argument against it was an official legal opinion which pronounced it "brutal and inhuman, and not excusable on any reasonable ground." It was further declared to be "illegal and unjustifiable" and to subject the surgeon to "the risk of a criminal prosecution."

These declarations, coming from a lawyer of high standing, led me to pay some attention to this view of the question, and I sought by conversation and correspondence with leading lawyers of my own State, to learn what principles of law, in the absence of specific legislation, had any bearing upon the matter. The question in its specific form seems never to have been adjudicated in any court of record.

In the case of a sane person, courts have uniformly held that if a surgeon possesses ordinary professional knowledge, exercises ordinary skill, and uses ordinary care in the management of his case, no action of malpractice can lie against him. It is, of course, presumed that, in case of an operation, the consent of the patient shall first have been obtained, both parties acting in good faith, and the patient understanding the object and character of the operation. As a matter of course, likewise, any operation for a criminal purpose, even though with the consent of the patient, would not be justified by the courts. Here, as elsewhere, the law is guided by common sense—in the words of an eminent member of the Illinois judiciary, "The law *is* common-sense." The only medico-legal questions, therefore, which seemed to me to apply here were such as had relation to what constitutes valid consent.

With this view I drew up three questions and submitted them to one of the professors in the Law Department of the University of Maryland. The answers which follow are clear and comprehensive, and seem to me to require no further comment.

BALTIMORE, MD., MARCH 6TH, 1893.

DR. GEORGE H. ROHE, Catonsville, Md.

*My Dear Doctor:*—After considerable investigation I am prepared to answer the several questions submitted to me by you in your letter of February 17th.

"1. Is an insane person, having lucid intervals of greater or less duration, competent in law to consent to a surgical operation upon his or her body, the result of such operation being removal of certain organs or members not essential to life or health ?"

During a lucid interval a lunatic is, in the eye of the law, sane. 19th. Cent. L. J. 427.

The act of a lunatic, during a sane interval, has in law the validity of the act of a sane man.

Pope Law of Lunacy, 18.

Am. & Eng. Enc. of Law, Vol. 2. 112.

Buswell on Insanity, Sec. 17.

I answer, therefore, in reply to the first question that a lunatic, in a lucid interval, is as competent to consent to a surgical operation of any kind as is any person.

Of course, you readily understand that great care is necessary in determining whether or no the consent is given when there is an actual lucid interval, and the law cannot relieve a physician from the responsibility of exercising this care.

"2. In case the person above described is incompetent to legally give consent for the performance of such operation, can the recognized, natural or legal guardians of such persons give consent described ?"

According to the theory of law, the State, acting through courts of equity, is the guardian of all insane persons, both as to their persons and property. The equity court appoints a committee as its agent for the discharge of this duty. Such committee is the legal guardian of the person, and has the power to consent to

such measures as may be for the lunatics benefit.

Pope Law of Lunacy, 111.

Md. Code, Art. 16, Sec. 96.

Rebecca Owings case. 2 Blands Chan. 272.

I answer, therefore, that the committee of a lnnatic is competent to give consent for the purposes mentioned, assuming, of course, that he and the physician act in good faith.

The law does not recognize any such person as a natural guardian to a lunatic. The father, and, if he be dead, the mother, is the natural guardian of an infant, but the term is not applied to those who have control of persons non compos mentis.

"3. In case a person is always entirely insane have the natural and legal guardians the right to give the consent described ?"

I answer on the authorities cited in the answer to the previous question that the committee of an insane person has the right to give the consent.

I may further add, that, even though the committee may refuse, an application to the court of equity, which appointed the committee, would be entertained, and it would be competent for the court to give the consent.

"4. In case neither the patient himself, or herself, or his or her guardians, are competent to give the consent described, has the attending physician the power legally to decide: that an operation, as described above, shall or shall not be performed. In other words Dare a physician perform an operation on an insane person if the latter has no relatives living or known ?"

In answering this question it is important to bear in mind that no person can be confined until he has been adjudged insane by proper proceedings, or unless he be dangerous to himself and others.

Pollock on Torts, 108.

Rebecca Owings case, 1 Blands Chan. 272.

Fletcher vs. Fletcher, 28 L. J. Q. B. 134.

Anderson vs. Burrows 4 C. & P. 210.

Lock vs. Deane 108 Mass. 120.

Underwood vs. The People, 32 Mich. 1.

And in the case where confinement is necessary, because a person is dangerous to himself or others, the restraint must be temporary, and further proceedings immediately taken.

Brown on Med. Jur. Sec. 30.

Commonwealth vs. Kirkbride &c., 2. Breste, 398.

It seems, therefore, clear that a lunatic with no committee cannot against his wishes be detained for any purpose except to prevent him from injuring himself and others, and that his confinement being for that purpose only will not authorize the performance of a surgical operation.

I answer, therefore, that a patient confined without a committee cannot consent to a surgical operation, and the attending physician has not the power legally to decide that an operation is to be performed on such lunatic.

In connection with this subject there are several matters to which I would call your attention.

Surgical operations upon insane persons place the operating physician in a position of delicacy for several reasons. If he relies on the consent of the lunatic he is charged with the duty of determining whether the lunatic is or is not insane at the time of giving the consent. And it is probably true also that insane persons, who recover, are strongly disposed to hold persons responsible who have confined them for insanity, or who may have performed surgical operations on them while confined. Yet the law appreciates the delicacy of this situation. It does not relieve the physician of his responsibility, and of his duty to act with propor caution. It is for this reason that the central principle, in the modern law of insanity, is that the validity of any act of a lunatic depends on his capacity to perform the particular act in question.

People Exrel. Norton vs. N. Y. Hosp. 3rd. Abb. N. C. 229.

The law would, therefore, not exact so high a capacity in a lunatic to consent to a surgical operation, as it would to enter into a contract.

State vs. Housekeeper, 70 Md. 162.

Thus it has been held that a lunatic is capable of being a witness, although not capable of entering into a contract.

3rd. Abb. N. C. 229.

The physician himself must calculate the chances involved, and assume the responsibility of the propriety of the operation, instead of leaving this to the patient as in the case of a sane man.

Ewell on Med. Jur. 289.

A part of the responsibility, which the physician must assume, is to determine whether the insane person has that degree of capacity requisite to consent.

Before closing you will permit me to make some general remarks suggested by my reading and thought on this subject. The law hedges about every person with certain protection to his person, and it makes it the normal rule that no person can in in vitum be even touched by another. *A fortiori,* a surgical operation cannot be performed on a person without his consent. The exceptions relate to persons who are incapable of giving consent by reason of defect of capacity from infancy or insanity. In these cases the power is in the courts of equity to give the consent, and this power the court may delegate to guardians of infants, and committees of lunatics.

There are, however, undoubtedly cases in which, where there is no guardian or committee, emergencies arise or circumstances exist, which make it impracticable to apply to a court of equity. In these cases the surgeon should act with peculiar caution. If there are friends or relatives of the lunatic, he should, as far as practicable, consult with them, and he should, as far as practicable, avail himself of the judgment of other physicians. If none of these are available, he may in cases have to act on his own judgment and responsibility.

This, in my judgment, after a full reading of the subject, is clearly the position in which the law leaves the matter, and I cannot see that it would be wisdom to change it. If the law gave the surgeon greater power it might constitute a temptation to carelessness or to indulge in experiments.

It may be said that in this class of cases the physician is peculiarly liable to be sued by persons who have recovered or partially recovered their reason. On the other hand it should be borne in mind that the tribunals before such suits are tried, are fully apt to take this fact into consideration.

Very truly,
RICHARD M. VENABLE.

# CLINICAL LECTURES.

## VALVULAR LESIONS OF HEART, PULMONARY ŒDEMA, OLIGOCHROMÆMIA, SIMPLE ANÆMIA.*

CHARLES G. STOCKTON, M. D.,

This patient is an American aged 34; married. When fourteen she had inflammatory rheumatism with chorea following. She has had tonsillitis every fall since then. Otherwise her health has been good until four weeks ago, when her legs began to swell and she had a cough accompanied by considerable expectoration. Her father was killed in the army, her mother and one sister died of heart disease; otherwise the family history is good.

The history of acute articular rheumatism followed by chorea and several attacks of acute tonsillitis, is significant in connection with the fact that the patient has at present bruits to be heard over various points in the præcordium. In all probability the bruits were present during the attack of chorea. It is possible, indeed common, for people to live many years without knowing that they have a valvular lesion; which is not, therefore, necessarily a serious thing. It becomes serious when, for any reason, compensatory hypertrophy of the heart does not occur. Aortic insufficiency is, of all lesions, the most difficult to be compensated for; next comes mitral stenosis. Mitral insufficiency and aortic obstruction are usually quite well compensated for, provided the heart is well nourished and well innervated. These requisites can be brought about by maintaining the general nutrition and innervation of the patient by hygienic surroundings, regular but light occupation, exercise, proper food,

*Record before the Buffalo General Hospital Medical Clinic.

sufficient sleep, and avoidance of excitement and dissipation. Freedom from acute and chronic diseases will enable a heart with valvular lesion to maintain its equilibrium when even a slight disturbance of the general health may be enough to retard the circulation, to produce pulmonary and general venous congestion, with cough, dyspnœa, dropsy, disturbed digestion, enfeeblement of the mental powers, etc. Sooner or later there comes a time when the equation between the valvular weakness and cardiac innervation and nutrition is lost. This hour may be delayed until the patient has reached the natural limit of years; it may follow a severe fever or a period of loss of sleep, overwork or excitement; it may be hastened by anæmia or some other constitutional state. It may be impossible to explain just why the cardiac power has failed at some particular time.

During a fortnight, our patient's pulse has rarely been below 90, while the temperature has ranged irregularly between 98.5° and 102°; the respirations have varied from 30 to 50. This record alone points to some trouble with the lungs, because the respirations are increased proportionately to the pulse and the temperature. We can rule out acute inflammatory diseases on account of the comparatively low temperature. Respiration means not simply the bellows action of the lungs, but the interchange of gases between the red corpuscles of the blood and the cells of the tissues. The rapidity of respiration depends not only upon the capacity of the lungs to supply oxygen to the red corpuscles, but largely upon the demand of the tissues for oxygen and their necessity of giving off carbon dioxide. It is, therefore, not strictly correct to connect an accelerated breathing with pulmonary disability. The respiratory centre in the medulla which calls the lungs into play is stimulated by the presence of carbon dioxide in the blood. You may remember that, some time ago, I brought a patient before you with nothing wrong in the lungs, and with apparently well oxygenated tissues, yet respiration was accelerated and this rapidity of breathing was explained as due to Bright's disease, the retained toxines irritating the respiratory center. I lately saw another case of rapid breathing occurring in connection with puerperal convulsions of renal origin. In this case also there was no pulmonary lesion. The poisons which excite the respiratory center may not cause any elevation of temperature. Overstimulation of the respiratory centre may occur independently of any toxæmia, and I have reported several cases of rapid breathing of most alarming appearance, in which no organic disturbance could be detected, and which yielded to remedies administered on the hypothesis that the trouble was a neurosis.

But, knowing from the history of the case, of the existence of a cardiac lesion, in all probability of long duration, we naturally ascribe the rapid breathing to some pulmonary affection secondary to the interference with the circulation. The damming back of blood into the lungs is liable to produce œdema, as it would in any other organ. The prolonged congestion may have established a condition of brown induration in addition to the œdema.

On examining this woman's lungs, we find rales, sibilant and sonorous breathing sounds—which should be spoken of as rales—an imperfect respiratory murmur at the bases; dullness on percussion at the bases, becoming gradually less as we go upward, where the respiratory murmur becomes clearer. The rales and the sibilant and sonorous breathing increase as we ascend. There is expectoration of frothy mucus. On the right side the dullness amounts almost to flatness at the base, and the respiratory and voice sounds are distant. There is undoubtedly a little hydrothorax here.

So we have to do with brown induration and œdema of the lungs, bronchitis and slight pleural effusion on one side. The urinary examination is negative.

On examining the blood with the hæmato-spectroscope, we find a clubbing of the oxyhæmoglobin bands in the spectral field, indicating that the blood is imperfectly oxygenated. Comparison of the blood with the color scale indicates that there is about sixty per cent. of hæmoglobin present.

The heart presents a double mitral murmur, showing that there is both stenosis and regurgitation, and dilatation is evident from the weak and wavy cardiac impulse discovered to the left of the nipple line.

The treatment is first to keep the patient warm in bed, in order to lighten

the labor of the heart. Dry cups should be applied frequently over the chest to relieve the engorgement of the lungs, and the surface circulation should be stimulated by frequent hot mustard foot baths and by diffusible stimulants if necessary. Why do I mention these means before speaking of digitalis, strophanthus and similar cardiac tonics? Because it is better to lessen the venous engorgement of the organs before stimulating the heart; because it is better to draw the blood from the lungs than to force it through them; because by so doing, we not only relieve the lungs but diminish the obstruction offered to the right heart, thereby directly benefitting it. The left heart is also benefitted by bringing blood into the superficial capillaries and thus reducing the pressure in the larger vessels. There is danger in giving digitalis when there is weakness of the left heart, overdistention of the right ventricle, and opposition to the circulation from the congested organs. There is the constant tendency to think of what medicine we shall give. I want to impress the lesson that we must think how best to relieve a diseased condition without having recourse to drugs, by physiological means, by mechanical, electrical, hygenic or other non-medicinal treatment. In pneumonia and various other pulmonary troubles some, men advocate the use of remedies that deplete because, they say, you can not safely stimulate the heart. On the other hand, there is a class who say that it is dangerous to deplete the system. A third and larger class occupy middle ground, and advocate in the beginning depletion and other means that lessen congestion and later stimulants to sustain the heart.

Thus the blood is coaxed or drawn along at first, then pushed or driven forward by digitalis or alcohol if necessary.

The next patient suffers from a high degree of simple anæmia. By *simple* anæmia, I mean one that does not depend upon any striking abnormality aside from that of the red corpuscles. We always find anæmia following malnutrition from any cause, such as indigestion in its various phases, absence of proper food, many acute and chronic diseases. In distinction from simple anæmia, we find a class of anæmias associated with diseases of other organs, for example the spleen, liver, bone-marrow and lymph-nodes. These anæmias usually have peculiarities besides the condition of the red corpuscles. In simple anæmia, the red corpuscles are much reduced in number; they may be greatly increased in size and distorted. There is a relative increase in the number of white corpuscles and there may be an insignificant actual increase. Much light can be thrown on the nature of anæmia by studying the change in the number, form and size of the blood bodies.

There is another form of anæmia that depends essentially not upon the changes mentioned but upon a fading out of the red corpuscles, that is a deficiency in the hæmoglobin. This disease is called chlorosis because the skin of those affected is usually of a greenish color from the presence of the separated coloring matter of the red corpuscles. This coloring matter—the hæmoglobin—after being carried in the plasma, settles in the various tissues of the body and undergoes chemical change. The liver is almost invariably much darker than normal from the deposition of this pigment.

This patient presents marked evidences of anæmia in the pallor of the face, the conjunctivæ, the lips, the tongue and the gums, in short of all the accessible mucous membranes. Gingivitis, glossitis, conjunctivitis and other inflammations may obscure the anæmic condition of these membranes and, similarly, a lividity of the face from some obstruction to the circulation or an increase in the local blood supply from some disturbance of the sympathetic nervous system may disguise the pallor which we would naturally expect. The last patient, for example, although suffering from a diminution of hæmoglobin to the extent of 40 per cent., presented no marked pallor, but on the contrary some lividity. Thus the color of the skin and mucus membranes can not be relied upon as strictly diagnostic of the richness or poverty of the blood in all cases. But when marked pallor is present in connection with other symptoms, the diagnosis may be made quite positively. This patient is short of breath, her pulse is rapid, especially after exertion, and even the excitement of appearing in clinic is not sufficient to cause a flushing of her face, in spite of the acceleration of the pulse. In the absence of organic disease of the heart, lungs and other viscera, such as were found or suspected in the first

patient, we must explain the acceleration of the pulse and respiration with reference to the condition of the blood. You remember that true respiration is carried on by the aid of the red blood corpuscles. In this case these carriers of oxygen are deficient in number and when the patient makes an exertion or becomes excited or in any other way calls for an activity of some organ, there is a demand for oxygen which can be supplied only by hurrying the red corpuscles through the vessels so that they may become recharged with oxygen in the lungs more frequently. Bearing in mind the importance of oxygen as a nutrient, you can readily understand that a deficiency of it, such as is inevitable in anæmia, will lessen the activity of every organ. There is commonly a sense of languor and an inability for mental exertion, there is a failure of the digestive power and the bowels are usually constipated. There is often a suppression of menstruation, which is conservative, since the body can ill afford a loss of blood. Even when the menses are not suppressed, as in the present case, they are deficient in color and usually scanty. For some reason that is not very clear, anæmia, especially when of high grade, is usually attended by a slight rise in temperature. This patient's chart shows a range between 98° and 101.5°. In special forms of anæmia, the temperature curve is quite typical, as in the intermittent temperature of leucocythæmia. In simple anæmia, the urine is usually highly acid, which is true in this instance. There has been considerable improvement in the last week, largely on account of treatment by iron. The girl has had one grain of Blaud's pills three times daily after eating. She is also taking alkalies, for in anæmia it is important not only to provide iron but to increase the alkalinity of the blood.

# COMMUNICATIONS.

## UTERINE THROMBOSIS FOLLOWING POST-PARTUM HEMORRHAGE, AND ITS RELATION TO PUERPERAL INFECTION.*

R. W. REYNOLDS WILSON, PHILADELPHIA.

Post-partum hemorrhage is followed by a series of consequences dependent upon thrombosis. The most conspicuous of these are phlegmasia alba dolens and pyæmic infection, although a general infection dependent upon the same cause is to be observed, as demonstrated by the histological study of the subject. In normal involution the contraction and retraction of the uterine muscle is sufficient to prevent bleeding from the sinuses by causing an approximation of the vessel walls. In the absence of normal uterine contractions, dependent upon want of muscular development, or upon loss of blood, as in placenta prævia, or upon over-distention from twins, or hydramnios, hemorrhage is prevented by the formation of the thrombi. On the part of the blood itself, the increase of fibrin, consequent to the loss of blood, is an important factor in thrombosis. This natural means for controlling hemorrhage approaches a pathological condition, in that it admits of an extension of the thrombi into the veins surrounding the uterus, namely, those of the parametrium and broad ligaments. In this way a direct communication between the endometrium and pelvic veins is set up.

In active involution the blood current is diminished, and the absorptive power of the veins and lymphatics is decreased, whereas in defective involution the amount of blood in the uterus increased, and the lympathic circulation called more actively into play. According to Winckel (1) the outcome of physiological thrombosis is described as a conversion of the thrombi by the immigration of wandering cells, pro-

* Read before the Philadelphia Obstetrical Society, May, 1893.

bably with the aid of the endothelium and vaso-vasorum, into a firm connective tissue cord, which at times becomes canaliculated, possibly by the passage of red blood corpuscles, so that the blood current is restored. Thus, under the conditions in which uterine inertia exists, we have hemorrhage giving rise to increased tendency to inertia and to the formation of thrombi, which serve as a dangerous means of communication with the central venous circulation, and as a stimulation of the lymphatics surrounding them. Where elements of infection are absent the thrombi shut off the uterine cavity from the circulation, but where septic material is present they offer, when once affected by the putrefactive changes about them, a means of entrance into the system for the micro oganisms which attack them.

Bacteriological research has shown that the normal uterine lochia contain no germs, and may be injected into the body of any animal in any amount without injury. Doderlein (2) found that after a normal labor with a temperature not exceeding 98.4° there were no germs, but when fever was present bacilli and cocci were found until the temperature fell, being eliminated by the very abundant secretion, especially when this was purulent. Micro-organisms may find entrance into the uterine cavity by various means, and when in contact with the endometrium give rise to infection. It has been positively shown that the endometrium is the usual source of infection, for in puerperal ulcers of the vagina we have only a mild form of infection accompanying the local signs, and although the same micro-organisms are present as those which are found within the uterus in puerperal endometritis, they occur only at the seat of infection, and are not found penetrating into the neighboring tissues (3).

Having, therefore, a case of hemorrhage with the occurrence of dilatation thrombosis and the presence of septic material, we have the liability of infection, the process attacking the endometrium and spreading by means of the disorganization of the thrombi along the course of the veins, especially at the placental site, and invading the general circulation.

It will be of interest to study the means by which infecting germs find entrance into the uterus. These may be present before the occurence of labor in cases in which hemorrhage is likely to occur, their presence and the liability to hemorrhage being dependent upon the same cause. Namely, in cases of endometritis we have, as has been so forcilby maintained by Pozzi, the presence of pathogenic organisms, the prevailing species being staphylococci (pyogenes aureus, albus and citreus), and various kinds of streptococci. As to the part played by the uterus in cases of hemorrhage due to metritis and endometritis with the presence of the usual pathogenic organisms, Winckel states that a limited metritis, or premature fatty degeneration of the muscles of the pregnant uterus is likely to interfere with the contractile power of the affected area. Endometritis having existed during pregnancy, and present at the time, when uterine contraction and retraction are essential to the arrest of hemorrhage, predispose to bleeding; first, on account of the hyperæmia; secondly, by reason of erosion of already occluded vessels from the presence of mycotic elements; and thirdly, by interferencence with involution. The question arises, what determines the presence of micro organisms within the uterus in endometritis, and why, if in any such case their existence is proven, should puerperal endometritis and its consequences be the exception rather than the rule? The answer to this lies in the fact that the tissues of the genital tract possess, under normal conditions, a power of resistance to the pathogenic action of the germs which may be present. The vitality of these germs becomes more and more attenuated as they are acted upon by the normal secretions and cellular elements of the tissues. This antagonism of the tissues against the invasion of pathogenic germs continues as pregnancy advances, up to the time of the beginning of labor. The completetion of labor, marked by the expulsion of the placenta and discharge of liquor amnii, affords the natural means by which the genital tract is flushed out, and the possibility of the lodgment of germs is prevented. In pathological conditions, on the other hand, that is, in simple endometritis, in contra-distinction to puerperal endometritis, the mucous membrane becomes infected by the invasion of germs which are indigenous to the genital tract. According to Pozzi (4) there exists in the genital tract of the female a zone rich in micro-organisms, situated at the level of

the internal os. The activity of this zone is increased by the general debility of all the tissues, which reduces cellular vitality, or by traumatism. In endometritis the mucous membrane becomes infected from this source, and the ordinary lesions and symptoms follow. In puerperal endometritis we may, in cases where hetero-infection may be excluded, ascribe the condition to an ante-partum infection dependent upon an earlier endometritis, the earlier pathological changes in the uterine mucosa and connective tissue predisposing to hemorrhage, by interfering with contractions, with infection of the resulting thrombi by the germs which are already present. In cases of atony from other causes (want of muscular development, over distention) the treatment which is used to avert the hemorrhage, and the necessary manipulations, may be responsible for the infection. Frequent examinations during the course of labor, hasty and careless manipulations at the time when the patient is bleeding, and carelessness of the principles of asepsis owing to the loss of self-control on the part of the attendant, and the introduction of infected instruments, all contribute to the risk of infection. There exist, therefore, under these circumstances, ample opportunities for the invasion of bacteria.

What, on the other hand, are the natural means of resisting these bacteria in cases of non-infection, and what are the local changes in septic cases, resulting from the action of micro-organisms? Immediately after the expulsion of the placenta the uterus contracts and obliterates the cavity recently occupied by the ovum. This contraction is influenced largely by the nervous condition of the woman, and may be considered as an active process. Under normal circumstances the innervation of the organ produces the active power of contraction irrespective either of the elasticity of the fibres or of the diminution due to shortening of the fibres by retraction. The blood supply is lessened by this contraction, and the vessels at the placental site are compressed by the uterine fibres and emptied of blood. Both the free contents of the uterus, namely, blood and the remaining amniotic liquid, and the adherent shreds of decidua are expelled. As soon as the tonic contractile power of the uterus is established, retraction of the muscle (fatty degeneration of the muscular fibres) and regeneration of the mucous membrane take place. Together with the lessening in size of the uterus by retraction, there is an increase in the development of intraglandular tissue and a reconstruction of the mucosa from the epithelium springing from the remaining glands. The exudation which accompanies this process, together with the migration of white corpuscles and the secretion from the cervical canal, constitute the lochial discharge. As to the local changes occurring in the course of infection, we have these normal processes modified as follows: First, as a predisposing cause of infection we have the absence of uterine contraction. As a result, the hemorrhage from the sinuses is controlled, not by pressure, but by thrombosis; secondly, the uterus contains, also incident to the absence of contraction, remnants of decidua, or placental débris, these, together with the thrombi projecting from the placental site, act as foreign bodies, and are prone to putrefactive changes; thirdly, the reconstruction of the mucous membrane is replaced by necrosis of the epithelium and basement membrane; fourthly, the normal constituents of the lochial discharge are replaced by the putrefactive débris of disorganized thrombi, the remnants of decidua and necrotic mucous membrane, mixed with the various micro-organisms which accompany these putrefactive changes. In order to appreciate the relation of such changes to the development of infection, it will be necessary at this point to study the histology of puerperal endometritis.

According to Bumm we have commonly to deal with the following forms:

*Putrid Endometritis.*—In this form putrefaction occurs from the presence of saprophytic organisms. The bacteriology of this condition is still undeveloped; as to the histology, we find that the necrotic decidua is cut off by a zone of cellular infiltration, by which the various micro-organisms present are prevented from penetrating into the underlying tissues. Invasion of the thrombi, however, at the placental site, is not prevented by any such zone of reaction on account of the want of organization of the thrombotic tissue.

*Septic Endometritis, occurring in two forms.*—First, a localized septic process in which a granulation zone occurs (con-

trary to what is found in the form mentioned above), shutting off the necrotic endometrium and preventing the invasion of germs. The uterine lymphatics are not actively involved. The placental site, as in the putrid form, is most markedly affected. Secondly, a septic endometritis, accompanied by a general infection. Bumm has studied five cases belonging to this class, and has found in three instances that infection has occurred by invasion through the lymphatic system, and in two instances along the course of the veins. In the first set of cases, the placental site is free from micro-organisms and thrombi, so that it is not likely that this pathological condition bears upon that form of infection resulting from hemorrhage in which thrombi, especially at the placental site, occur. In the second set of cases, the smaller lymphatic branches surrounding the sinues are marked by colonies of cocci, which extend into larger lymphatics underlying the peritoneal covering of the uterus. The decidua is disorganized and infiltrated with a fibrinous exudate, presenting a diphtheritic appearance. In this class of cases, as well as in that about to be described, the granulation zone is absent. This fact has evidently an important bearing upon the function of such a zone of demarkation, in combating the progress of micro-organisms into the underlying tissue.

Thirdly, *a thrombotic form of infection*; and this is the form which concerns us principally in the discussion of post-hemorrhagic infection. This is characterized by both a putrid and septic endometritis. It is described by Bumm as follows:

"The decidual layer of the uterine cavity, in a state of necrosis, is beset with micro-organisms. In the neighborhood of the colonies of streptococci, outlined by the staining process, are scattered innumerable colonies of putrefactive germs. The histological relations of the tissues—that is the decidual, glandular, and muscular tissues in the necrotic area—is unrecognizable."

The zone of reaction is marked. The placental site presents no remains of the placenta, but is marked by the projection of thrombi. The latter are found to be infected by various pathogenic germs, are disorganized, and offer, by reason of their disorganization, a direct means of entrance for the septic products into the current of the blood. The disorganization occurs first in the axis of the thrombi. The endothelium and the vessel wall become rapidly affected and break down into a mass of necrotic tissue mixed with white corpuscles and infected with cocci and bacilli.

In conclusion, we may summarize the development of infection as a result of thrombosis by noting the following events: First, a predisposition to infection arising in cases of hemorrhage the result of atony of the placental site; secondly, the formation of thrombi which offer, on account of their want of vital organization, an improper means of resistance to infecting germs; and thirdly, the presence of infecting material either from the pre-existing endometritis or from contamination at the time of delivery by careless or frequent examinations. When these factors are present we have a resulting infection occurring in accordance with the histological changes described above.

Clinically we are apt to consider pyæmia as the type of infection occurring as a result of thrombosis. Such a view is based upon, first, the frequency of the occurrence of phlegmasia following phlebitis, either by extension from the veins of the broad ligament or by the lodgment of coagula washed from the placental site and carried into the hypogastric veins and obstructing the flow of blood through the crural veins; and, secondly, upon the occurrence of embolism from the detachment of thrombi from the placental site or the parametrium. But it is more likely, from the histology of endometritis in the puerperal state, that the thrombi act more as a channel by which pathogenic germs find entrance into the organism than as a direct means of conveyance by their detachment and circulation in the blood-current. We have observed in the thrombotic form of endometritis that the disorganization of the thrombi is a pathological change dependent upon the action of bacteria, and that the natural barrier to the entrance of infecting elements is removed by this process of disorganization. According to this, the blood-current is likely to be contaminated, not by the remnants of uterine coagula, but by the presence of pathogenic bacteria and their chemical products. These, carried along in the blood-current, may be reasonably supposed to set up inflammatory changes, causing

phlebitis, and especially to produce the development of a general septicæmia. There is no doubt that the formation of emboli is a common result of the detachment of thrombi from the placental site, but, in the study of the subject from a histological point, we are not warranted in accepting the occurrence of pyæmia as the universal clinical associate of thrombotic infection the result of hemorrhage, and, on the other hand, we are warranted in assuming the possibility of a marked state of septic endometritis occurring after hemorrhage without the early association of pyæmic symptoms.

# THE TREATMENT OF LARGE OVARIAN CYSTS, WITH THE REPORT OF A CASE; EXTIRPATION OF THE COCCYX FOR CONGENITAL CYST.*

EDWARD P. DAVIS, M. D., Philadelphia.

It is my purpose to night to report the clinical histories of these cases, inviting discussion upon them by the members of the society.

Case I, of large ovarian cyst, occurred in the person of Mrs. V——, aged 55 years, seen by me in consultation for an abdominal enlargement. The history of the case was briefly as follows: The patient had been of extraordinary muscular development; by occupation a market-woman, she had enjoyed exceptionally robust health. At a time not accurately described by herself and family, she first noticed an enlargement of the abdomen; this must have been three or four years before I saw her. This enlargement was painless, slowly increasing, and had been variously diagnosticated as dropsy and tumor. The diagnosis of ovarian cyst had not been stated to the patient, although it may have been made by some of the numerous physicians who saw her.

When I first visited her she was undergoing treatment for the relief of dropsy, this treatment consisting in the administration of a diuretic mixture and the occasional employment of purgative medicines. On examination, the patient was markedly emaciated above the sternum; her thighs were moderately swollen, her legs less so than her thighs; her arms were wasted. Her expression was not markedly cachectic, and a typical ovarian face was not clearly developed. Her pulse varied from 100 to 110; her respiration was not noticeably difficult; she was cheerful, complaining of no pain, but of the increasing load and drain upon her muscular strength, occasioned by the abdominal enlargement. She was unable to lie down, resting in a partly reclining posture, usually on the right side. She could not sit upright, as the abdominal enlargement had descended so far as to protrude between her thighs. She was taking a fair amount of nutriment, and complained of no pain. She strongly desired to know the nature of her disease, and, if possible, to have the size of the abdominal enlargement decreased, or the condition radically remedied.

A superficial examination of the abdomen by palpation, and a partial vaginal examination, convinced me that a positive diagnosis could not be readily made under the circumstances in which I found the patient. She was accordingly told that it would be unjustifiable to even puncture her abdomen in her own house, and that a proper diagnosis and treatment of her condition could only be obtained in a hospital, where antiseptic precautions were possible. She was accordingly brought to the Polyclinic Hospital some time afterward, it being necessary to place her in a partially recumbent position, in a wagon to transport her to the hospital.

*Read before the Obstetrical Society of Philadelphia, May 1, 1893.

She was there examined by my colleagues, Dr. Baer and Dr. Morton, and by my friend, Dr. George E. Shoemaker. The following condition of the abdomen was observed:

Its enlargement was very great, and is best shown by the photographs done by Dr. White, of the resident staff, which I show to the Society. The skin of the abdomen was brawny and thickened, and at the first sight simulated closely some of the hypertrophies of the integument occasionally seen; indistinct fluctuation was obtainable upon the left side of the abdomen, while at the right and upper portion a sensation of greater resistance was detected. Vaginal examination was negative, as the tumor descended so far externally that it was very difficult to make a satisfactory investigation. It was learned from the patient's daughter that she had had, in the preceding few months, several attacks of syncope, which had occasioned considerable anxiety among the family. A diagnosis was made of probable ovarian cyst, and an exploratory incision, and, if practicable, the removal of the tumor, were advised. The patient's family were informed that her death in a short time was unavoidable if she was not relieved; that the chance of saving her life was questionable, and that the only relief lay in surgical interference, probably of a radical nature. It was observed that the patient retained remarkable muscular power, being able to partially raise herself and move about upon her bed in a manner indicating her former strength of physique and constitution. She and her family consented to the operation, and after suitable preparation, with the assistance of Dr. Shoemaker, Dr. Morton and Dr. Baer, the abdomen was opened.

To place the patient in position for operation it was necessary to provide an additional table for the tumor. As she could not lie upon her back she was turned upon her right side, the tumor lying upon a small table. As syncope was feared, oxygen was at hand, and an electric battery and various stimulants. It was determined to mitigate the tremendous change in the physical conditions of the circulation, which the emptying of the tumor would produce, by removing the contents as slowly as possible, making continuous pressure during this time. An incision through the abdominal wall revealed, as was expected, the sac of a cystic tumor. This was punctured by a trocar, when a large amount of chocolate-colored fluid escaped. More than a half hour was consumed in emptying the fluid, the patient meanwhile enduring the operation fairly well. The cyst was but very slightly adherent to the wall of the abdomen, and it seemed quite possible to completely remove the tumor; accordingly, the tumor was separated from the abdominal wall. It was found to be a multilocular cyst, its largest portion lying beneath the liver. The solid parts were broken down as rapidly as possible, and the entire mass removed. Its pedicle was from the right ovary, and was so small as to scarcely require ligation. No adhesions calling for ligature were found, and the hemorrhage which accompanied the separation of the cyst was inconsiderable.

The patient partially collapsed during the removal of the solid portion, but was relieved by inhalations of oxygen and the use of an electric battery, accompanied by the injection of stimulants. The removal of the tumor demonstrated the great changes which its enormous size had caused in the body of the patient; the lower ribs had been turned outward and upward, and the distended abdominal walls lay in folds against the spinal column.

As quickly as possible the abdominal cavity was freely flushed with a hot saline solution, the incision closed and large masses of cotton were bandaged firmly above an antiseptic dressing. The patient reacted from the operation, her temperature being 97.5° and then 98°; her pulse 120 and 130. She became conscious and complained of no pain. Six hours later, without appreciable warning, she died in sudden syncope.

No post-mortem examination could be obtained, but symptoms of hemorrhage were never present. The condition of the patient's kidneys and bowels was normal before and after the operation.

The solid portion of the tumor weighed nine pounds; seventeen gallons of fluid were collected during the operation, the weight of the fluid being 17½ ounces to the pint. The total weight of the solid and liquid portions of the tumor reached the great total of 160 pounds. Microscopic examination of the fluid showed cholesterin and hæmatin, blood cells and anomalous epithelia. No measurements were made of the tumor before its removal, as

the patient's condition was such that I limited manipulation and disturbance of her position to the interference necessary in securing an examination for diagnosis.

The question of practical interest suggested by this case lies in the avoidance of the syncope which destroyed the patient's life. Is it possible to remove so large a mass from the abdominal cavity without producing such a change in circulation as to cause fatal syncope? Two methods of treatment were available one the partial emptying of the cyst, stitching its wall to the abdominal wall and using drainage; the second was the complete removal of the cyst as practiced. Had firm adhesions been present, no effort would have been made to remove the tumor; it would have been partially emptied, with the hope of prolonging the patient's life by the operation. The fact that the tumor could be separated without great difficulty from the abdominal wall led us to practice total removal, believing that the patient's chance of ultimate recovery would be sufficient to warrant the procedure. We were led to operate upon the case by the patient's desire for relief, by the threatening syncope from which she had already suffered, and by her remarkable and persistent strength, and her previous history of uniformly good health.

Case II is an example of abscess over the coccyx without appreciable cause, and accompanied by pain at the sacro-coccygeal joint, completely relieved, first by evacuation of the abscess, and then by extirpation of the coccyx. The patient, Mrs. B., was first seen in the eighth month of her first pregnancy; her health had been good; her pelvis was normal; the fœtus occupying the second position, its heart-sounds were plainly discernible. She complained of a painful swelling to the left of the coccyx and above the junction of coccyx and sacrum. This swelling gave indistinct fluctuations, and was painful upon pressure. On vaginal examination, pressure upon the coccyx revealed great tenderness, also to the left of the articulation with the sacrum. She stated that, three months previously, a similar swelling had appeared, which was dissipated without treatment. She said that, before her marriage she had been fond of riding, but at times had been obliged to dismount by reason of pain in this region. When asked if she could recall a bruise, fall, blow, or direct injury to the part, she could not do so. Under antiseptic precautions the tumor was incised, emptied of an ounce of foul, sanious pus, and a careful examination with the finger and probe was made to detect caries of the bone. This was apparently absent, a smooth cavity only being found. A pyogenic membrane was curetted away, the cavity irrigated and packed with gauze. Uninterrupted recovery followed.

At the patient's labor she experienced marked pain when the head reached the pelvic floor. Her child, a female, was small, and the delivery was readily accomplished under anæsthesia by chloroform. Her puerperal period was marked by no complications.

Five months after her labor she requested further relief for pain in the coccyx. Previous to her marriage she had been a trained nurse, understood the details of surgical operations, and desired to avoid any such procedure if possible. I could detect no hysterical element in the case, but the patient and her husband were convinced that treatment was requisite.

On vaginal examination the gential tract was found in a normal condition; the patient's general health was excellent; the position of the uterus was normal, but pressure upon the cervix gave rise to an indistinct, grating sensation and to the complaint of acute pain upon the part of the patient. The coccyx was accordingly removed, and found to be of normal length and dimension. The articulation between the sacrum and coccyx was slightly roughened, but no evidence of caries, necrosis, or suppuration could be found. The scar of the previous abscess was firm, and the abscess had been completely obliterated. The patient was entirely relieved by the removal of the coccyx, and continues in good health.

The interesting point in regard to the case is an explanation of the occurence of this abscess when the history of no spetic infection could be obtained. The usual causes of abscess in this region are violence, sinus, or fistula connecting with the intestine, and septic infection of the genital tract, septic infection after labor, accompanied by mechanical injury to the parts; by the fœtus, or the instruments used by the obstetrician. The most rational explanation of this case is afforded by the interesting examples found in surgical

literature, where abscess cavities without communication with surrounding parts have been observed in this region of the body, as the result of a persistence of the fœtal medullary canal. Most of these cases occur in males, and hair is found in these cavities. The continued irritation of the parts by pressure has explained a non-septic necrosis which results in the formation of abscess in this region. In many of these cases an external opening is found near the coccyx, admitting a small probe from which a sinus proceeds along the walls of the intestine. Pavement epithelium is often found upon the walls of these cysts when hair is not present. Cases similar to that reported have been reported by Terrillon, Goodsall, Warren and Beach. An interesting research upon this subject is that by Mallory, of the Harvard Medical School, published in the *American Journal of the Medical Sciences* for March, 1892, page 263. The relation of such sinuses and cysts to the coccyx is well shown by Mallory in reproductions of microscopic sections through embryos of various ages.

## CLINICAL OBSERVATIONS IN PHILADELPHIA.

W. H. LINK, M. D., Petersburg, Ind.

Having lately passed some three months in Philadelphia, studying the materials, methods and results that obtain among the great surgeons of this city, I shall try, through the medium of the Reporter, to set forth the advantages and disadvantages of Philadelphia as a place for post-graduate study for those men of the West and South who every year migrate toward the great medical centers of the country seeking the latest and the best in both medicine and surgery.

In the first place Philadelphia is cheap. Both board and lodging are exceedingly low. One can find good accommodations ranging from $4.50 to $6.00 per week. Instruction is given at moderate prices. To a man of wealth these things would be of no special importance; but the average country doctor is not noted for the large and increasing size of his bank account, and the meanest thing about him is his income. The length of his stay will thus depend largely upon the cost of living.

Philadelphia offers superior advantages for the study of abdominal surgery. In this branch she excels. There is not a man in her confines doing abdominal surgery as a specialty who is not a superior operator and teacher. The abdominal surgeons, too, take great delight in showing their work. Every facility for close and accurate observation is offered visiting physicians. The amount of material is apparently inexhaustible. If one will arrange his engagements properly, he may see from three to ten sections a day. In a twelve-weeks' course he can see the whole field of abdominal surgery covered—tumors, pus cases, hysterectomies, liver surgery, gut work, hernias, anything and everything to which pelvic and abdominal surgery comes for relief or cure.

If one stays in Philadelphia three months and takes advantage of his opportunities, and then goes home and fails to do good abdominal work, it will be due to defects inherent in himself rather than to a want of good and sufficient teaching.

The general surgery of Philadelphia, taken as a whole, is not so good as that of the gynecologists, and a great many of the general surgeons manifest but little desire to have their work observed. There are, of course, brilliant exceptions to this rule, which I will notice further on.

The Polyclinic has two admirable surgeons on its staff, who do a large amount of work, and as the classes are usually small at any one time, attending physicians have abundant opportunity to study each case and every operation at close range and master both the principles and diagnosis and the technique of the operation.

Dr. B. F. Baer holds a clinic three days in the week at the Polyclinic Hospital, and always has something of interest to show the class. Baer's methods of teaching cannot be improved upon. The class, small in number, are each permitted to

examine the patient, make a diagnosis and prescribe the treatment. He then discusses the case with them and corrects any errors that have been made. If an operation is indicated, the class get a close view of the work and are thus permitted to study the case both from below and above. The old speculum system of teaching, or the Ferguson peep-show, has no place with Baer. As an operator, Baer holds an enviable position. His results are very good, and he throws open the wards of the hospital and invites inspection of his cases in their convalescence. Baer has some ideas of his own, which place him in a solitary position among the abdominal surgeons of Philadelphia.

He opposes drainage, as a rule, and he undoubtedly practices what he preaches. He very rarely drains. I saw him remove huge pus tubes and ovarian absceses during which the pelvic cavity was bathed in great quantities of pus. He irrigated carefully and closed without drainage. The patient made a prompt and painless recovery. He also gives morphia if his section cases suffer pain. He does a supravaginal hysterectomy, which is a most beautiful operation to look at. The operation consists in tying off the ovarian and uterine arteries, cutting the uterus away at the crevix and covering the retracted stump with the peritoneum by means of a few Lembert sutures. The only question about the operation is its mortality. He has twenty-seven cases with two deaths. If he can keep his mortality this low it will compare favorably with the operation by the nœud and give a quicker convalesence.

What one sees in Baer to approve, are his self-reliance, his courage, his thoroughness, his practical methods of teaching and his splendid results. To appreciate him at his worth, one should see him operate often. At first, he seems to be indecisive, hesitating, but as you see more of him, you find that what appeared to be nervousness and vacillation is only a species of somnambulism in which he merely thinks aloud and goes on with the work while talking to himself. His underlying strength and skill soon rise to the surface and when the work is complete you behold in the finished product a conquest that bespeaks a master. There are some minor things in Baer's technique that one might criticise, but, in the face of such splendid results as he shows, criticism seems akin to carping, so I refrain.

Dr. J. M. Baldy operates at both the Polyclinic and Gynecean Hospitals. His work is to be commended for his faultless technique as to asepsis and his boldness as an operator. He is very cool and collected and does not lose his head however trying the complication that may arise. Baldy is especially free from hobbies. He does good plastic work and I think shows good sense in doing Emmet's operation on the perineum without attempting to spoil a most beautiful and perfect piece of surgery by some modification of his own. We have yet to see anyone modify Emmet's works who did not convince us that the modification greatly marred the beauty and efficiency of the work. Baldy is one of the most fluent talkers at the Obstetrical Society and as a writer and teacher he makes himself easily understood. As to his results I cannot speak, as I saw none of his cases after operation, but presume that they are good, for his surgery was both clean and skillful. Both Baer and Baldy are warm admirers of the Trendelenburg position. They use it in most of their work and certainly the position, in their hands, appears to great advantage. In deep hemorrhage especially, it seems to supply a long felt want.

Dr. Joseph Price has a daily clinic in the diseases of women at the Philadelphia Dispensary. He does most of his surgical work at his private hospital, 241 N. 18th St. In this hospital he has about 90 beds and when crowded can make room for one hundred beds. Besides his work here, he does a great deal of consultation work both in and out of the city.

Large numbers of men come to observe Price's work. They represent every state in the Union and every one of the Canadian provinces. A great many stay and observe for a short time, whilst others take a course with Dr. Price of from six to twelve weeks. For this he charges from one to two hundred dollars. In this course the student-doctor makes a diagnosis and prescribes treatment at the dispensary. If the case is surgical, he assists Dr. Price to operate. All the operations are most carefully and thoroughly demonstrated. During the twelve weeks that I was with him, he did from two to five sections a day, and frequently as many as three plastic operations in one day.

He is a great operator, and, what is better, a great teacher. His technique is the simplest and most perfect it has ever been my good fortune to observe. His diagnostic skill is a marvel to those who have a chance to see it exercised. He operates for positive disease only, and not for any troubles that cannot be identified and located by the tactus. In all the numerous sections observed by me in his practice, I never yet saw him open the belly for anything but the most positive and easily demonstrated disease. His skill as an operator is so great that the work he does seems to the bystander easy till he tries it himself. He never, at any time or under any circumstances, loses his head or becomes in the least rattled. If a trying hemorrhage unexpectedly occurs, the only evidence of its effect on him is an increase of moisture on his brow. He uses but few instruments and the leading characteristics of his work are simplicity and the most absolute cleanliness. So perfect is the drill that he has put himself through, that when from any cause his hands are soiled, they appear like a fish on dry land and seem uncomfortable and instinctively move toward the water. He operates as a skillful musician plays the violin, his fingers always find the proper position at the right time, but it has been done so often that the action has almost become automatic and scarcely requires an effort of the mind and will. His sections now number over two thousand, while his mortality is near three per cent.

He has done 85 extra-uterine pregnancies with one death, and his mortality in hysterectomies is 5 per cent. While I was with him he had but three deaths at his hospital, and saw the patients daily, after section, until they left for home. Dr. Mordecai Price, the brother of Joe, is also a great surgeon, whether judged by his knowledge, operative skill or successful results. He is now doing almost as much work as his brother, and is doing it just as well. Both of these men do a large amount of plastic gynecology, and while their abdominal work is almost beyond criticism, their plastic surgery is simply a beautiful exhibition of the surgeon's art. They both do Emmet's operation on the perineum and believe it the best operation of the kind ever developed or perfected for the purpose. They give Emmet full credit for his work, and do not attempt to rob him of his just dues by a useless or harmful modification of their own. The fact is, Emmet has done for plastic gynecology in America just what Tait has done for abdominal surgery in England, and it would be much better for suffering women if those who offer them surgical relief would take the work as Emmet has perfected it and not mar a really beautiful procedure by some fancied improvement of their own. The work of the Prices is daily increasing and they are now doing over 600 sections a year. This may seem a large amount of work, but when we remember that they draw their material from British America to Cuba and from California to Massachussetts, that patients come to them from every State in the Union, it will not seem so large. They have no idle moments and know no Sunday.

The general surgery of Philadelphia is no discredit to her old-time reputation. But since the days of Agnew, Pancoast and Gross some changes have crept in. Then the best and most brilliant work was done by the old men. In fact, Agnew's success all came to him after 45. Now with probably two exceptions, Morton and Keen, the really valuable, original, brilliant and successful work is done by the younger men. Roberts, Deaver and White are all worthy to wear the mantle of any of Philadelphia's great surgical teachers of the past.

Dr. J. William White is professor of surgery in the University. He is a natural teacher and no one is readier to recognize it than the students who sit under his tutelary wing. He is a clear, fluent and instructive lecturer. His operative skill impresses all visiting physicians so favorably that they desire to see all of it possible. Dr. White is a great stickler for antisepsis; but his antisepsis is not an excuse for slovenly technique, for it is joined to the most perfect asepsis.

Being a personal friend and a great admirer of Sir Joseph Lister and Mr. Fredrick Treves, he believes strongly in the virtue of germicides but does not neglect cleanliness. The fact is, White's aseptic precautions, and the automatic exactitude with which he applies and observes them in his work, would ensure success in the most difficult abdominal surgery. In Dr. White are most happily combined

the brain of a cultured surgeon and scholar with the body of an athlete, and to the *mens sana in corpore sano* is added in the freest manner the polished manners of a gentleman. His kindness and courtesy to visiting surgeons are tireless, while nothing exhausts his patience.

Should one desire to work a short time in a good clinic and under an able specialist and teacher in diseases of the nose and throat, he will find all that he may wish at the Pennsylvania Dispensary, cor. 13th and Chestnut Streets. The nose and throat department of this dispensary is in charge of Dr. J. L. Hammond. He is one of the rapidly rising young men of the city. He has marked diagnostic skill, and as a manipulator of instruments and a teacher of others he certainly has few superiors. Dr. H. while working at this specialty wisely devotes himself to general practice, and this broadens and deepens his knowledge against the day when his practice will be so large that he will be compelled to confine himself to a special line of work.

There are hospitals and dispensaries and schools enough in Philadelphia to keep any number of post-graduate attendants busy from morning till night if they were systemetized so that hours and days would not conflict. But so long as only a few men exhibit a desire to show their work, a very large amount of valuable material must of necessity go to waste.

---

## ABDOMINAL HYSTERECTOMY WITHOUT A PEDICLE, WITH REPORT OF TEN CONSECUTIVE CASES*

RUFUS B. HALL,† M. D., Cincinnati, Ohio.

The best methods of treating the pedicle in abdominal hysterectomy has been a subject for contention for years. There have been two principal methods which have been universally accepted—the intra-peritoneal and the extra-peritoneal, and for a number of years one or the other of these has been recognized as the orthodox plan.

As we might naturally expect, there have been many modifications and improvements in minor technique of Schröder's and Pean's methods, as originally practiced by them. As our knowledge of the pathological conditions and complications to be overcome in removing fibroid tumors increased, and our operative experience became broader and more mature, the Pean method of extra-peritoneal fixation of the pedicle became the one which was almost universally employed. For this reason it will be the method most frequently used in making comparison in this paper. The cause of the extra-peritoneal method being the one most frequently employed is obvious when we recall the fact that only a small percentage of all fibroid tumors are suitable cases for treatment by Schröder's method, by those advocating it, and of these it was not possible to control hemorrhage in all cases; and, above all, the Pean method gave the best results.

Those of us who have made many abdominal hysterectomies for the removal of large tumors know that the tumor may, and not infrequently does, descend into one of the broad ligamants and body of the uterus so far that we must separate it from its peritoneal envelope before a suitable pedicle can be made and fixed outside. Manifestly, these complicated cases are not suitable ones for the intra-peritoneal method, even by the most ardent advocates of it, and have, therefore, heretofore been treated by the extra-peritoneal method by most operators. We are all aware of the fact that, if we use the intra-peritoneal method, we are in great danger of losing our patient from intra-abdominal hemorrhage; and, if we use the extra-peritoneal method, we not infrequently see the pedicle slough and become a menace to the life of the patient for days afterwards, and not a few die from septic infection from that cause. If the patient makes a primary recovery from the extra-peritoneal method she is not in all cases restored to health. She not infrequently suffers great pain,

* Read by title at the American Medical Association, 1893.

† Professor of Clinical Gynecology, Miami Medical College.

due to the pedicle dragging upon the abdominal scar and pressure upon the distorted pelvic organs interfering with their functions because of the fixation of the pedicle. The prolonged and painful convalescence which necessarily follows this method is a very serious objection to it, and not infrequently a hernia follows the operation, at or near the point where the pedicle was fixed in the abdominal wound.

If we can remove these objections without additional risks to our patients, it is our duty to do so. Thanks to the ingenuity and skill of American gynecology, we have now a method which promises all of the advantages of both of the old methods, with but few of their disadvantages.

It was one of these desperate cases, in which the operator had to "enucleate large nodular masses from the broad ligament," that induced Eastman to remove the entire cervix in his first total extirpation operation. The success in that case encouraged him and others to continue making the operation, improving the technique in minor details until it is very near, if not quite perfect. The procedure has distinct merit over all other methods, and it is upon this basis we ask a hearing before the profession at this time.

First: There is no pedicle to become necrotic, and thereby a source of septic infection, or fatal hemorrhage.

Second: There is no more danger from hemorrhage than after ovariotomy.

Third: There is no more raw surface left in the peritoneal cavity to favor intestinal and omental attachments than after ovariotomy.

Fourth: It is no more difficult than many other abdominal and pelvic operations, and does not require any more time to perform it.

In patients with thick abdominal walls this method promises as good results as in those with thin abdominal walls, which cannot be said of the extra-peritoneal method. There is no distortion of the pelvic organs, thus interfering with their functions. There is a comparatively painless convalescence, which is shortened at least two weeks under that of the extra-peritoneal method.

These are a few of the advantages of the method as suggested to me in my experience with it.

There is not as much danger of hemorrhage as there is in simple ovariotomy, from the fact that in the latter operation the pedicle is transfixed and ligated in mass; and in not a few cases the pedicle is short and thick, with great tension upon it, favoring the slipping of the ligature and hemorrhage. In total extirpation the broad ligaments are divided from the uterus and ligated in sections which are not put upon the stretch, therefore there is but little if any danger of a ligature slipping off. The ligatures do not include any uterine tissue, therefore the tissue within their grasp is not susceptible to undue shrinkage and resulting hemorrhage. There is no raw surface left in the pelvic cavity after the operation is completed, except the ovarian stumps, to form attachments to intestine or omentum.

After ligating off the ovaries upon both sides, the peritoneum only is divided about one inch above the top of the bladder, across the front of the tumor and at a corresponding heighth on the back of it. This is done before any temporary clamp is placed. The peritoneum is then stripped down in front and the bladder separated from the tumor down to the vagina, and the peritoneum stripped from the tumor behind. All of the ligatures required in the subsequent steps of the operation are placed so as not to include the peritoneum in their grasp. The number of ligatures in any of my operations has not exceeded three upon each side after the peritoneum was stripped down. One end of each ligature securing the uterine arteries is left about six inches long, and after the cervix has been removed, is carried out through the vagina, and are cast off or removed through that passage. The peritoneal edges which were stripped from the tumor are now turned in towards the vagina and neatly coapted from one ovarian stump to the other by a running stitch, thus closing off entirely the raw surface in the vagina from the peritoneal cavity. The wound in the vagina is treated the same as after an ordinary vaginal hysterectomy.

The difficulties attending the operation are not so great as one who has not attempted it would suppose, and they are easily and rapidly overcome by one skilled in performing difficult and complicated abdominal and pelvic operations; and the

time required to perform the operation is no longer than that required to make many of the difficult abdominal and pelvic operations now being performed daily.

It has been said that by the removal of the cervix the key of the arch of the pelvis is destroyed, and a weak point is the result, which will in a certain percentage of cases result in vaginal prolapses or hernia. Such an accident has not followed the operation, to my knowledge, neither has it occurred after vaginal hysterectomy; and I do not believe it would occur any more frequently after abdominal hysterectomy than vaginal hysterectomy, where the two conditions after operation are identically the same; and we do not hear of objections to the latter operation on that account.

The method has stood the test admirably fulfilling every indication and requirement even better than its friends had anticipated. I am convinced that the method has come to stay, and in the near future the clamp in abdominal hysterectomy will as certainly be a thing of the past, as it now is in ovariotomy.

I make this assertion advisedly, knowing full well that it is a radical one which is not likely to be readily assented to by many operators. In proof of my confidence in the method, I here give a short report of all the cases I have operated upon by this method, ten in number.

Many of the cases were very undesirable subjects for any operation, and most of them proved to be complicated operations as you will see, thus testing thoroughly the merits of the method.

Case 1. Mrs. W., aet 50. Referred to me by Dr. Joseph Eichberg of this city. Operated upon February 4, 1892, and a tumor weighing 22 pounds removed. There were firm and extensive adhesions to to intestines and omentum and abdominal walls, as well as in the pelvis. There was an abscess in the pelvic cavity holding a pint or more of pus. This abscess was ruptured and its contents spilled inside of the peritoneal cavity during the operation. Patient recovered and is now in excellent health.

Case II. Mrs. P., aet 52. Referred to me by Dr. Means, of Troy, Ohio. Operated upon March 31, 1892. The tumor extended to one inch above the umbilicus. She made a rapid recovery and is now in good health.

Case III. Mrs. F., aet 37. Referred to me by Dr. Templeton, Covington, Ohio. Operated upon September 11, 1892. At that time patient had been suffering from septic peritonitis for 12 days, caused by the strangulation of a pedunculated portion of the tumor the size of a small orange. At the time of the operation, pulse 138, temperature, 103°. There was a pint or more of dark colored fluid in the peritoneal cavity. The tumor was a large one, extending up to the ribs. The patient made a prompt recovery and is now in good health.

Case IV. Miss H., aet 42. Referred to me by Dr. J. G. Senour, of Troy, Ohio. The physician of a neighboring city removed the ovaries and tubes June 3, 1892. This operation failed to check the growth of the tumor or the hemorrhage. A few months after the operation the hemorrhage was worse than before. The tumor filled the entire pelvic cavity and projected well up into the abdomen. The operation was made December 2, 1892. The bladder was carried up almost to the top of the tumor and had to be dissected from it. There were extensive and firm intestinal adhesions to the left side of the tumor, corresponding to the point where the ovary had been removed. In the right side of the abdominal and pelvic cavities there were many adherent coils of intestine which were separated with the utmost difficulty. One coil was adherent behind the tumor deep down in the pelvis to the stump from whence the right ovary had been removed, and had to be separated by the sense of feeling before the tumor could be delivered. The intestine was intensely lacerated in liberating it. The peritoneal covering of the intestine at the point of injury was entirely stripped from it, and the adhesions were so firm and extensive that it was impossible to trace out the intestine to a healthy portion so as to make a resection. The intestinal injury was repaired with sutures, but could not be brought up so as to make an artificial anus. The patient rallied well, and in three hours had a pulse of 70, and a temperature of 99°. But to my very great regret the fluid removed from the drainage tube had a eculent odor, showing conclusively that the intestines at least leaked gases. The patient died the 5th of December from septic peritonitis, due to intestinal leakage. The death was not due to any fault of the

total extirpation method, and the result would have been the same by any method of treating the pedicle, as it was plainly due to intestinal leakage.

Case V. Miss J., aet 39. Referred to me by Dr. Blair, Lebanon, Ohio. The tumor was a soft œdematous fibroid. Profuse hemorrhage. Operation March 9, 1893. Patient made a prompt and uninterrupted recovery.

Case VI. Miss M., aet 40. Referred to me by Dr. Rhu, of Marion Ohio. Tumor extended well into the abdomen and was firmly adherent in the pelvis. Operation March 16, 1893, after an attack of acute peritonitis of fourteen days duration. Patient recovered.

Case VII. Mrs. T., æt 44. Came to the clinic of the Miami Medical College for treatment. The tumor extended to three inches above the umbilicus. Pain and hemorrhage. Operation at the Presbyterian Hospital, March 30, 1893. Patient made a prompt and easy recovery.

Case VIII. Miss S., æt 39. Referred to me by Dr. Blair, of Lebanon, Ohio. Large, soft, œdematous fibroid of sixteen year's standing. Tumor extended about four inches above the umbilicus. Profuse hemorrhage, great anæmia, and extreme weakness. Operation April 29. Prompt recovery.

Case IX. Mrs. B., æt. 33. Referred to me by Dr. Heaty, of Glendale, Ohio. Profuse hemorrhage and severe pain. Operation May 15, 1893. Tumor size of cocoanut. Double pyosalpinx and suppurating ovaries with six ounces of pus on left side. Universal adhesions. Patient recovered.

Case X. Mrs. N., æt. 52. Referred to me by Dr. Dewitt, this city. Profuse hemorrhage for three years. Tumor extended three inches above the umbilicus and was firmly fixed in the pelvis. Great pain and marked anæmia, and extreme weakness. Operation May 23, 1893. Extensive intestinal adhesions, large suppurating ovary holding eight ounces of pus, which was ruptured and its contents spilled inside of the cavity during the operation. Patient recovered.

I have heretofore been so prejudiced against the operation of hysterectomy that I have refused to operate as long as the patient's condition could be made tolerable. But with the present good results following total extirpation, I shall hereafter advise operation earlier for fibroids. Considering the nature of the cases constituting this report, the results are all, or even more, than could be expected.

---

**The Weight of the Two Sides of the Brain.**

Prof. Braune, of Leipzic, has recently published the results of weighing the halves of 100 human brains. These were divided in the median line, and the cerebellum, with the medulla and pons, were cut off and bisected. The weight of the two sides of the whole encephalon were compared, as well as that of the cerebral hemispheres, and the halves of the cerebellum with the medulla and pons. It has generally been taught that the left half of the brain is heavier than the right, and that this is a physical cause of right-handedness. The results of Prof. Braune's investigations do not seem to bear this out. He found the left side of the entire brain heavier in 52 cases, and the right in 47 cases, the two sides being equal in one case. And he also found that if the excess of weights of the two sides be added up, the right side showed a preponderance, the difference between the two sides being in most cases so slight as not to deserve any consideration. In five cases in which the right side considerably outweighed the left, the bodies were examined for signs of left-handedness, but none were found. The left cerebral hemisphere was the heavier in 54, the right in 37 cases; while the left side of the cerebellum was the heavier in 54 and the right in 33 cases. Thus he found that the cerebral hemisphere of one side is the larger about as often as the cerebellum of the other; but the larger halves are on the same side about twice as often as on different sides.—*Boston Medical and Surgical Journal.*

An exchange publishes the following bill-head of a doctor in Kansas: "A prompt settlement of this bill is requested. If bills are paid monthly a discount of ten per cent. is allowed. Bills not paid monthly will be passed to my attorney for collection. If you pay your doctor promptly, he will attend you promptly, night or day, rain or shine; while your slow neighbor suffers and waits, as he made the doctor wait, and while he is waiting the angels gather him in."

316-18-20 North Broad Street,
PHILADELPHIA.

**TERMS**:—Five Dollars a year, strictly in advance, unless otherwise specifically agreed upon. Sent three months on trial for $1.00.

**REMITTANCES** should be made payable only to the Publisher, and when in sums of Five Dollars or less, should be made by Postal Note, Money Order or Registered Letter.

**NOTICE TO CONTRIBUTORS**:—We are always glad to receive articles of value to the profession, and when used they will be paid for, or reprints supplied, as the author may elect. Where reprints are desired, writers are requested to make a note of that fact on the first page of the MS. It is well for contributors to enclose stamps for postage, that the articles may be returned if not found available.

SATURDAY, JULY 15TH, 1893.

## EDITORIAL.

### MEDICAL ASSOCIATIONS.

Men are gregarious. They work best by division of labor. Individuals differ in capability for achievement as in capacity for enjoyment. Methods and tastes are as varied as individuals are numerous. It is by aggregation that the common weal is best conserved, the weakness of one being supplemented by the strength of another and the benefits of superior strength or skill diffuse among the many. A general average is thus maintained which prevents the social organism becoming lop-sided or top-heavy. The resultant of many and diverse forces is constant and uniform in direction and accomplishes what would be impossible to the individual. Countless diversities massed into a homogeneous power, a force irresistable by presenting obstacles. Association, like a smelting furnace, reduces to shining metal the gross crude ore alike with delicately-wrought filagree works of art.

For mutual encouragement, for mutual help, for the greatest good to the greatest number, medical associations are organized. Their philosophy should be preeminently utilitarian and Jerremy Bentham should be canonized as patron saint.

The greatest good to the greatest number is the motto most worthy to be engraved upon their official seals.

Bacon says, "reading makes a full man, writing an exact man, and speaking a ready man." To read in order that one may observe intelligently, write accurately and speak readily and exactly is a most laudable ambition. But without personal association there is no audience to whom to address what has been written, and no intelligent ears to receive ideas when spoken. Discussion brushes away cloudy ideas, crystalizes nebulous hypotheses, sharpens the wit, gives command of a vocabulary, makes comprehension easy, and compels close study and advised speaking. One will carefully scan facts and their relations if they are to pass through the flame of criticism and will

make knowledge his own before subjecting it to the keen scrutiny and ready and sharp criticism of assembled fellows who accept nothing as gold because of its glitter.

Ideas beget ideas, as steel strikes fire from flint. The very discussion of the subject insures its closer study; thus self-improvement carries with it an extension of benefit to all who appear within the charmed circle. The assembling of large bodies of men interested in the same subjects and pursuing similar lines of thought kindle enthusiasm, arouses ambition, stimulates investigation, and often fixes the attention on interesting parts of the work which had hitherto been overlooked in the eager pursuit of other parts. Personal association broadens the mind, elevates the thought, and developes love for the less sordid aspect of daily professional tasks. To the conscientious practitioner the annual society meeting takes him from the labor and anxieties of his round of toil, gives a much needed variation to his life, and affords rest and recreation. At the same time it brightens up his armor by the attrition of friendly minds one upon the another. He goes back to duty refreshed and replenished, and made stronger in every sense of that word.

Our object then in the organization of a medical society should be the pursuit of knowledge, the development of mind, the strengthening of purpose, the evolution of truth and the general elevation of the standards of professional honor and professional acquirements. In doing these things a certain mutual touch of mind and a communion of spirit beget broader views and inspire more enthusiastic investigation, the glamour of philanthopy may crown the dryest of facts, and the prophet's vision vie with the poet's dream in connecting the commonest acheivements of the present into the immeasurable blessings of the future.

So long as a medical society keeps before it only these ulterior objects, so long as it ignores politics and advertising, just so long is it a great boon to the rank and file of the profession. Let work, and work only, year by year, draw the members together and power for good will increase as time rolls by; but the very moment men forget these ends and begin to organize small cliques for office and advertisement, a great black mark is placed across the fairest escutcheon and men begin to spend time in laying pipe and working for votes and influence. Bitterness and strife and backbiting appear and the hard working and simple member to whom such things are disgusting drops out and looks elsewhere for the mental pabulum that he is disappointed in finding. Let the offices and all such emoluments be conferred upon the very old men who can fill a chair gracefully and fairly though they may no longer be desirous of taking part in the laborious work of writing papers and leading the discussions. The position of president or presiding officer is but an empty honor and ought to be the reward of long service if it is valued as a reward. Young men should be content to lead the battle against disease. If Nestor is present, let him preside, Achilles and Ulysses can fight and talk. Age in the chair commands and deserves respect, while on the floor age may not always be synonymous with wisdom.

---

### Gonorrhœa.

A committee of the Therapeutical Society of Paris reported favorably on the use of the urethral bougie of M. Weber in incipient gonorrhœa. This bougie is prepared as follows:

℞

| | |
|---|---|
| Gum arabic in powder | 15 pts. |
| Lactose | 5 pts. |
| Glycerine | 1 pt. |
| Iodoform | 2 to 4 pts. |

M. Make ten bougies 13 cm. long.

Bougies thus prepared are soft and supple. They should be introduced at night, on retiring. They melt in the urethra, and are expelled without effort in urinating.—*Med. Review.*

## REPORT OF THE COMMITTEE ON LEGISLATION.

[Advance Sheets of the Transactions of the Medical Society of the State of Pennsylvania.]

The Legislative Committee respectfully reports that it has at last been able to secure the passage of an efficient medical act by the Senate and House of Representatives of Pennsylvania.

By the provisions of this law, which still awaits the approval of the Governor, no one can enter upon the practice of medicine in this State after March 1,1894, unless he or she has a competent common school education, has received a medical diploma, and has been granted a license to practice medicine and surgery by the Medical Council of Pennsylvania, after an examination by a State Board of Medical Examiners.

Applicants for license, who have received their medical degrees after July 1, 1894, are not eligible for examination and license unless they have attended three courses of medical lectures in three different years ; and those who have received their medical degrees after July 1, 1895, are not admitted to examination for license unless they have studied medicine for a period of four years, three of which must have been in college.

The Committee believes that few,if any, States of the Union have laws which will protect the public from medical incompetence more efficiently than this enactment of the Pennsylvania Legislature; and it therefore congratulates the public and the profession on the successful outcome of the work undertaken nine years ago by this Society.

A short history of the efforts of the Society may here be of interest.

At the meeting held in Philadelphia May, 1884,various resolutions were offered by Dr. L. M. Gates, of Scranton, Dr. Edward Jackson, then of West Chester, now of Philadelphia,and Dr. John B. Roberts, of Philadelphia, having for their purpose a separation of the teaching of medical students from the examination and licensing of intending practitioners of medicine.

During the fall and winter of the same year, committees of the Philadelphia County Medical Society and of the Medical Jurisprudence Society of Philadelphia, in conjunction, formulated a bill establishing a State Board of Medical Examiners and Licensers, which was presented to the Legislature for enactment at the session of 1885. A copy of this bill was subsequently presented by Dr. Roberts, for the consideration of the Section on State Medicine of the American Medical Association, at the New Orleans meeting in the spring of 1885,and was referred by that section to the general meeting of the Association. The Association thereupon passed a resolution advocating the establishment in every state and territory of a State Board of Medical Examiners and Licensers, directed the Permanent Secretary to transmit a copy of the proposed law to each state society, and requested each state society to report upon the subject to the Association in 1886.

In consequence of this action of the American Medical Association, the Medical Society of the State of Pennsylvania had before it for discussion at the Scranton meeting in 1885, not only the report of its committee on the "Best Method of Granting the License to Practice Medicine," but also a completely drafted bill. Much attention was, therefore given to the subject, and a committee was authorized to prepare a bill for presentation to the Pennsylvania Legislature. At the Williamsport meeting in June, 1886, the committee reported a bill modeled to some extent on that proposed and advocated by the Medical Jurisprudence Society of Philadelphia, which had been sent to the Society by the American Medical Association as above detailed. The original bill had been introduced in the Legislature of 1885, as has been mentioned, but had failed to become a law.

Since this action successive committees of the Society have been earnestly engaged in organizing the profession, for the purpose of educating the public as to the necessity of medical legislation to protect the citizen from medical ignorance; and bills have been introduced at each session of the Legislature only to meet with successive defeat.

The present committee was authorized to have the bill, adopted by the Society at the Harrisburg meeting of last year, introduced in the Legislature convening January 1st of this year (1893). It accordingly had the bill introduced in the

House of Representatives by Hon. Henry K. Boyer, and in the Senate by Hon. Charles A. Porter. The committee, in addition, published and distributed a twenty-eight page pamphlet, showing the constitutionality of such legislation, the need of a law in this State, and the favorable view of the bill held by many representative physicians, who, from all sections of Pennsylvania, furnished the committee with written approvals. In this pamphlet were also published resolutions unqualifiedly endorsing the bill passed by the faculties of the Jefferson Medical College, the University of Pennaylvania, the Woman's Medical College of Pennsylvania, and the Philadelphia Polyclinic.

When the bill had been before the Legislature for two and a half months, it became evident to the committee that its earnest and unremitting efforts would be unavailing, and that the bill as then drafted could not be enacted into law. The passage of the bill as introduced was vehemently opposed by the sectarian physician of the State and by certain gentlemen belonging to medical schools and county medical societies in affiliation with this Society. Although your committee might have been able to have secured the passage of your bill against the wishes of one of these forces, it could not accomplish the work against such a combination of antagonistic agencies.

On March 19th, 1893, therefore, the committee held a conference meeting with prominent officers of the Society and representative members of the faculties of the University of Pennsylvania, Jefferson Medical College, the Woman's Medical College of Pennsylvania and the Philadelphia Polyclinic. As a result of this conference the committee decided that to modify the bill in such a manner as to secure the passage of a law, similar to that which has been so satisfactorily operative in the State of New York, was wiser than to permit the open and hidden enemies of higher medical education to rejoice at having once more defeated the Society's efforts to give Pennsylvania an effective medical law. It was also thought that if a medical bill was not passed at this session of the Legislature, it was probable that there would be little chance of any such legislation being effected for many years to come.

Accordingly the bill which passed both houses of the Legislature last week (May 10th) was substituted for the original bill, and successfully pushed to final passage. A copy of the law is appended to this report. Its provisions are briefly as follows:

From March 1st, 1894, the Medical Council of Pennsylvania shall have control of the examination and licensing of all physicians intending to enter upon practice in the State.

The Medical Council shall decide as to the competency of the preliminary education of intending practitioners and as to their moral character; and must require them to have a medical diploma confering the full right to practice all the branches of medicine and surgery. Diplomas granted to such applicants after July 1st, 1895, must have been obtained after four years medical study, three of which years must have been in college.

When these facts have been satisfactorily proved by affidavit, the applicant for license pays a fee of twenty-five dollars and is referred for examination to one of the three State Boards of Medical Examiners, which substantially act as committees under the supervision of the Medical Council.

The three State Boards of Medical Examiners are appointed by the Governor from the members respectively of the Medical Society of the State of Pennsylvania, the Homœopathic State Medical Society and the Eclectic State Medical Society; and consist each of seven members.

The applicant makes a choice of the Board by which he wishes to be examined; but the questions must be the same before the three Boards in all branches except materia medica, therapeutics and practice of medicine. The Medical Council, moreover, selects the questions for all examinations from lists of questions submitted to it by the three Boards of Examiners. The examinations must be in writing and the questions, answers and marks preserved for reference.

The Medical Council, having received notice that an applicant has passed a successful examination, issues its license, with the seal of the Commonwealth attached, to the candidate, if he be adjudged by the Council to be duly qualified to practice medicine and surgery.

The Council fixes the standard of qualifications, and has a veto on all rules and

regulations adopted by the three Boards of Examiners. It may issue licenses without examination to physicians licensed by Medical Examining Boards or Boards of Health of other states.

The Medical Council consists of the President of the State Board of Health and Vital Statistics, representing the medical branch of the State Government, the Attorney General, representing the legal department of the Government, the Superintendent of Public Instruction, representing the Educational department, and the Lieutenant Governor and the Secretary of Internal Affairs, representing the Legislative and Executive departments, and finally the Presidents of the three State Boards of Medical Examiners.

The Committee, in closing this lengthy and perhaps tedious report, wishes to express its heartiest thanks to Hon. Henry K. Boyer and Hon. Charles A. Porter, who introduced the Society's bill in the House of Representatives and the Senate, respectively, and also to those physicians and other members in both Houses; who, by their counsel and advocacy of the bill, rendered incalculable aid. In this place it is also proper to express its great obligation to Hon. Frank M. Riter of the House of Representatives and Hon. John B. Showalter of the Senate; who two years ago so actively advocated the passage of the bill introduced by this Society.

When the bill had very nearly reached the point of final passage, it was found that the committee's expenses would exceed the appropriation made by the Society for its use. The members of the committee, however, concluded that they would bear the additional expenses personally, rather than permit the bill to fail, after the Soctety had so nearly reached the goal for which it had been striving for nine years. All bills paid by the Society have been scrutinized by the Secretary of the Committee, approved by its Chairman, and then sent to the Publication Committee by which orders have been drawn on the Treasurer as required by the laws of the Society. The expenses incurred by the Committee, in excess of the appropriation will be something less than one hundred and fifty dollars.

Since the work assigned to the Committee has now been practically completed, the Committee respectfully asks to be discharged.

All of which is respectfully submitted.

H. G. McCORMICK, *Chairman.*
W. MURRAY WEIDMAN,
J. W. MOORE,
I. C. GABLE,
C. L. STEVENS,
W. S. FOSTER,
JOHN B. ROBERTS, *Secretary.*

[The law to which the above report refers was published in the MEDICAL AND SURGICAL REPORTER, June 3, 1893.—EDITOR.]

## CORRESPONDENCE.

### "THE POINTS OF SIMILARITY"

TO THE EDITOR: Dr. Roberts' discussion of "The Points of Similarity between us and Homœopathic Physicians" in the issue of the REPORTER of May 27th, is interesting and suggestive. The obvious criticism might be offered—which casts no reflection on the author of the excellent paper—that whether the statements made are viewed as an apology for or an elucidation of the actual practice of Homœopathy, they might have come more appropriately from a member of the Homœopathic school. It would seem that the members of a medical sect which represents the objection of a small minority of the profession to the general principles of therapeutics followed by the majority, would, ipso facts, be placed on the defensive. Until the homœopathic school was organized, there was really no such thing as a *school* or sect of medicine in the present sense of the term. There were individual differences of opinion both as to theory and practice, there were national and local jealousies in the days when narrow-mindedness and bigotry pervaded

all ranks of society, but whatever general organizations of physicians existed were based on a common interest in a common life work. Perhaps it is the natural sympathy for the "under dog" that occasions the popular sentiment of antagonism to anything that savors of hostility to the "new school." Even those of the laity who are not avowedly attached to Homœopathy wonder that physicians should expect from one another less of open rivalry and more of occurrence in opinions and methods than do those engaged in other professions and business. But for several reasons it is desirable that the medical profession should be united. The results of their work to the community at large are of transcendent importance, since health and life, instead of wealth and convenience are at stake. Financial errors may be rectified, imperfect handicraft corrected or restitution made, wrong legal opinions revised and decisions appealed, but, on the part of the physician and surgeon, a mistake, or a failure to adopt the best possible method is seldom without evil result and is usually irrevocable. Again, while a merchant can entrust almost everything, except the general supervision of his affairs, to subordinates whom he can hire for six to fifteen dollars a week and can feel satisfied if his business is carried on with financial honesty and success, the physician's money-making though important, is nevertheless, trivial in comparison with the labor of scientific study and careful practice. Every detail of his strictly professional duties must receive his personal attention and must be done accurately. He is continually confronted in his patients with problems which require a familiarity with chemistry, physiology, anatomy, psychology, bacteriology, microscopy, pathology, medical jurisprudence and other branches of study and a practical experience which no one man unaided can acquire. Physicians therefore, more than any other body of men are interdependent and grow to feel that every doctor who is not with them is against them.

The laity are inclined to draw comparisons between schools of medicine and religious sects. The analogy holds good to the extent that the homœopathic school was a splitting off of a small body from an originally undivided profession, but there are the marked differences that in medicine there never has been fixed creeds except those adopted by dissenting sects, nor has the regular school been bound to any formalism other than the code of ethics, which is simply an application of the Golden Rule and general principles of honor to special cases, and to which, as Dr. Roberts observes, no serious objection is offered by Homœopaths. Moreover, a man's goodness or badness, religiously speaking, depends not so much on the correctness of his dogmas as upon his intentions, while medical practice is good or bad according to whether the ideas which it follows are right or wrong.

A closer comparison can be made to the legal profession, in which, at present, the term *school* (in the sense of sect) is utterly meaningless. If, however, at some future time a number of lawyers should organize into a sect opposing the common construction of law and the customary practice of the majority of the profession, their attitude would be analogous to that originally assumed by the disciples of Hahnemann, and it would be simply a question of numbers and influence whether they would be considered a coterie of visionaries or whether they would succeed in splitting up the legal profession into schools.

It is not now appropriate to enter into a discussion of the merits or demerits of Homœopathy. A great point will be gained if the laity can be taught to regard medical sectarianism as intrinsically evil, to be justified only by strong dissenting convictions. If they can be made to appreciate that it is something more than dollars and cents that actuates the demand of the regular profession for a concentration of medical effort and thought, we shall, at least, not be condemned for declining to extend the right hand of fellowship to sectarians. If the tenets of Homœopathy can be plainly presented to the laity, if Homœopathists can be driven from their attitude as martyrs to the cause of mild doses and medical renovation, and pinned down to a defense or renunciation of Hahnemann's teachings, then we can trust the common sense of our non-medical fellow citizens to choose wisely, in the main, between regular medicine on the one hand and sectarianism on the other.

Dr. Roberts has confirmed by abundant testimony the growing sentiment that the

homœopathy of to-day has practically cut loose from the restrictions of Hahnemann, and that it is to a great extent parasitic upon the medical teaching and literature of the regular profession. Far from being creditable to homœopathy, these facts carry with them the odium which must always attach to any individual or society whose avowed principles and proctices are at variance. This is a period when religious denominations are revising their creeds and eliminating inconsistencies between nominal and actual beliefs. Let the homœopathic medical profession institute a general and formal inquiry as to what its tenets really are, and let it then proclaim them publicly in such plain terms as to obviate any future misunderstanding. My personal opinion is that such a general sifting of the homœopathic school would divide it into four parts. First, a few surviving believers in the original high-attenuation homœopathy would be found; secondly, there would be a larger percentage of honest adherents to a modified homœopathy, men whom we may esteem as friends and as citizens, but whose medical practice would be unqualifiedly different from our own; thirdly, there would be a goodly number of men who are unfortunately prevented from being one with us by the difficulties in the way of gaining membership in formally-organized bodies of regular physicians, or by an attachment to early associations, but who are homœopaths only in name, and who regret the inconsistent attitude in which they have placed themselves; lastly, there would be the chaff of the winnowing, a considerable, though not large, proportion of men and women who call themselves homœopaths to secure a share of an established practice, or because they think that the mental association of homœopathy with small and pleasant doses will prove profitable. These are creatures who are homœopaths for what the name is worth, and who would be eclectics, vitopaths or magnetic healers, if the financial outlook was better in any of these directions.

I agree most heartily with Dr. Roberts, that all obstacles should be removed from the way of these men, who, without sectarian beliefs, find themselves in sectarian societies and wish to unite with the regular profession; but it does not seem to me that the accidental wandering of homœopaths from homœpathic standards brings them into harmony with the organization which they still antagonize under the falsely applied name of allopathy.

A. L. Benedict.

174 Franklin st., Buffalo, June 30, '93.

---

Editor Medical and Surgery Reporter: Dear Sir:—There is a little point in Anæsthesia that I have never seen mentioned in any communciation on the subject, and yet is of such importance that it might not be amiss to call attention to it in a brief paragraph.

In many cases of anæsthesia at any stage there may occur long, deep sighing respiration. This may take place, and frequently does, immediately after an attack of vomiting or after slight evidence of return to consciousness, though it is just as apt if not more so, to occur during deep anæsthesia. It is not evidence of returning consciousness, but is exactly similar to or the same as that which takes place during or after periods of intense concentration during the waking period, as is commonly seen in churches, theatres, etc. It is an unconscious effort to inhale more air, and shows a defective or careless respiration. My only object in calling attention to this phenomenon is to advise all anæsthetizers to do what I have seen very few of them do. Remove the inhaler instantly and allow nature that which she is endeavoring to get.

This is where the disadvantage of an immovable apparatus comes in. It is possible that the amount of anæsthetic which may be drawn in from a saturated inhaler by one of these deep sighing respirations, during deep anæsthesia, might be just sufficient to carry the patient over the line. I would like also to give in my evidence against the custom of largely increasing the amount of vapor during and after attacks of vomiting with the idea of controlling the vomiting, especially is this dangerous in the later stages of the anæsthesia or operation.

Yours very truly,

Wm. H. Burr,

216 W. 9th St., Wilmington, Del.

If some men would get nearer to the Lord, they wouldn't have to make so much noise in church.

Don't try to carry all your religion in your head.

# ABSTRACTS.

## THE DRIP SHEET.

In a recent address before the New York Academy of Medicine (*Medical Record*), Dr. Weir Mitchell gives the following directions for the use of this agent by persons needing the modified rest-cure:

"What I dread most at the start, in all cases for rest, is grave insomnia. Whether it be accompanied by a state of mild mental excitement such as we all know, or is a pure incapacity to go to sleep or to stay asleep, or whether it be in popular medical belief a congested state, I am apt at once in bad cases to use twice a day lithium bromide, at first in thirty-grain doses, at noon, at 6 and 9 P. M., given in the malt or not, and soon decrease grain by grain. If I want a positive aid at bedtime, I prefer sulfonal in hot water. But of greater value are some of the hydro-therapeutic devices—and best of these is what is known, or not known, as the 'drip sheet.' Just how this is to be given is of the utmost importance. The following memoranda must answer to show how careful one must be in my opinion, as to these details. I give it here, in brief, much as I do to the patient not under the immediate care of a nurse. I cannot help adding that several of the most useful of the water processes are neither taught in our schools, nor so accurately in hydro-therapeutic text-books as to be of much value to the general practitioner.

*Memoranda for Use at Bedtime of Drip Sheet.*—Basin of water at 65° F. Lower the temperature day by day, by degrees, to 55° F. or to still less. Put in the basin a sheet, letting the corners hang out, to be taken hold of. The patient stands in one garment in comfortably hot water. Have ready a large, soft towel and iced water. Dip the towel in this, wring it, and put it turbanwise about the head and back of the neck. Take off night-dress. Standing in front of patient, the basin and sheet behind, the maid seizes the wet sheet by two corners and throws it around the patient, who holds it at the neck. A rough, smart, rapid rub from the outside applies the sheet everywhere. This takes but two minutes or less. Drop the sheet, let the patient lie down on a lounge upon a blanket, wrap her in it. Dry thoroughly and roughly with coarse towels placed at hand. Wrap in a dry blanket. Remove ice-wrap, dry hair, put on night-dress. Bed, the feet covered with a flannel wrap.

If all this seems to you, as you read it, too absurdly minute, I shall feel some regret. Yet believe me, it is worth the trouble, and the drip-sheet is a remedy past praise. If it fail, a pack may succeed; but this is more familiar to you. I doubt if the use of the drip-sheet is as well known.

---

The Indications for the Enucleation of an Eye are thus summarized by Jackson (*Philadelphia Polyclinic*):

1. The presence in the eye of a malignant new growth, as glioma, sarcoma, or tuberculosis. This indication is imperative, no matter how much vision the eye retains.

2. The presence in the eye of a foreign body, with iridocyclitis. If the injury be recent and the inflammatory process still active, and the patient cannot remain under observation, an eye with anything less than thoroughly useful vission should be sacrificed.

3. The presence of a foreign body in a blind eye.

4. Blindness with diminished tension of the eyeball, following perforation either from traumatism or corneal ulcer; most urgent after traumatic perforation of the exposed portion of the sclera.

5. Blindness from irido-choroiditis without perforation of the eyeball, if the patient cannot remain under observation.

6. Sympathetic inflammation, provided the exciting eye does not possess vision sufficiently good to be weighed against the chances of the sympathizing eye.

7. The actual presence of sympathetic irritation; not the risk of it, unless the patient is likely to be out of reach of surgical aid.

8. Persistent pain in a blind eye, sufficient to annoy its possessor or tempt him to the use of analgesic drugs.

9. Serious disfigurement of a blind eye, even if free from pain or risk of causing sympathetic disease.

# CURRENT LITERATURE REVIEWED.

THE AMERICAN GYNECOLOGICAL JOURNAL for June.

Dr. Thomas H. Manley reports a

**Fibro-Myoma of the Uterus and Broad Ligament of Forty-five Years' Duration.**

The woman lived to be 76 years old. The tumor had been examined by numerous physicians, few of whom agreed on a diagnosis, the opinions ranging between ovarian tumor and hypertrophic fibrosis of the right lobe of the liver. At one time she was under the care of Dr. Gunning Bedford, and was very desirous of having an operation performed for relief; but, owing to his influence, it was not done. The case demonstrates that, under certain circumstances, the presence of a uterine fibroid is not incompatible with longevity. In the end, though greatly reduced in volume, yet it still persisted as a foreign body, was an inconvenience to her while she was on her feet, and was a constant menace to her comfort while in bed. At the post mortem it was noticed that no trace of the uterus remained, nor anything like a normal ovary. The abdominal muscles had atrophied as the result of the continued pressure. In his remarks on the treatment of uterine fibroids, the author says that nothing in the way of direct surgical treatment should be recommended till we have first given constitutional and local measures a fair trial. He thinks that electricity possesses useful properties, but denies that it will dissolve and scatter away a calloused old fibroid. The electro-puncture should be interdicted. When the cervical canal is short and the tumor low down in the pelvis, the cervix can be dilated and the tumor removed *en masse* or piecemeal. Especially may this be done in the case of submucous or intra-uterine tumors. The author thinks it a mistake to teach that metrorrhagia is never absent in cases of fibroid tumors, as he has seen cases in which the patient never had any hemorrhage. Hysterectomies for fibroids are justifiable when they have destroyed the uterus, particularly with those of advanced years. Abdominal hysterectomy is a highly valuable operation in skilled hands and under proper surroundings.

Dr. W. F. Metcalf presents "A Report of Two Cases of Marginal Eczema," in which local treatment was of no avail till after the sexual organs had been put in good condition. In one case an ovarian growth was removed, in the other a lacerated perineum was repaired.

Dr. C. G. Jennings contributes a paper on

**The Induction of Labor in the Albuminuria of Pregnancy.**

His experience leads him to look upon albuminuria as a very grave complication of pregnancy; one demanding from the physician the utmost care and the best judgment to bring to a favorable issue. Termination in the complete disappearance of the albuminuria before the end of pregnancy is, in his opinion, unusual. While the statements of many writers show that women frequently go to term and through labor without disaster, to permit her to run the risks to both herself and child of acute renal insufficiency seems rarely justifiable. In mild albuminuria before the seventh month, the case should be put upon proper medical treatment and carefully watched. If the conditions improve or remain stationary, interference may be delayed until it is certain that the child stands a good chance of living, well on in the seventh month. In severe albuminuria before the seventh month, with marked renal insufficiency and dropsy, labor should be induced as soon as it is seen that medical measures have little or no beneficial influence. These cases probably always terminate in spontaneous premature delivery, with the death of the child or convulsions. In albuminuria occurring after the seventh month, labor should be induced if the condition remain stationary after a week or two of proper medical treatment. Daily examinations of the urine should be made, and any marked increase in the albumen or a decided decrease in the urine solids should be followed by prompt interference. In severe cases seen for the first time during the seventh or eighth month, and showing a decided decrease of urine solids and much dropsy, artificial labor should be promptly induced.

Dr. R. B. Maury reports "A Case of Ovarian Pregnancy." The specimen was referred to Dr. Alan J. Smith for an opinion, and he reported it an undoubted case of true ovarian pregnancy.

Dr. B. E. Hadra presents "A Contribution to the Pathology of the Fourchette." Dr. A. W. Hitt discusses "The Proper Treatment of Laceration of the Cervix." The remaining paper is by Dr. Joseph Price, entitled, "Gynecology and the General Practitioner," and has been published in THE MEDICAL AND SURGICAL REPORTER for May 13, 1893, page 717.

---

THE AMERICAN JOURNAL OF THE MEDICAL SCIENCES for July. Dr. F. Forchheimer contributes a paper on

**The Intestinal Origin of Chlorosis.**

The author concludes, as the result of experiments upon animals, that the number of red corpuscles is diminished in the veins of the intestine, while the quantity of hæmoglobin remains the same; therefore, hæmoglobin is absolutely increased in the vein and each red corpuscle carries more hæmoglobin in the vein than in the artery. From this observation the conclusion can be drawn that, in the rabbit, hæmoglobin is taken up by the blood from the intestine, and that it must be formed either in the parts supplied by the arteries—i. e., the mucous membrane in its broadest sense—or within the intestinal

canal. The author states in conclusion, that possibly some other origin for hæmoglobin may exist than in the intestine; from all evidences, however this is the principal source and in chlorosis the most important. He presents the results of the treatment by salol or hydro-naphthol (so called). No iron was used. The object of the treatment was to prevent abnormal decomposition in the intestine. The number of cases is too small to draw any conclusions from but the results were good.

Drs. Theodore Diller and J. J. Buchanan report

**A Case of Sub-cortical Cyst of the Lower Part of the Left Ascending Parietal Convolution.**

The case confirms, as much as a single case can, the generally accepted ideas concerning the localization of certain motor functions in the Rolandic region. It lends support to the opinion (upon which there is not so much unanimity) that there is no cortical representation of sensation in the pre-central convolution, and also offers distinct negative evidence in support of the view that this convolution is not related to the function of muscular sense. The hypothesis of Seguin, Mills and others, that when hemiparesis precedes spasm the lesion is sub-cortical is confirmed by the evidence presented by the case. From the surgical aspect of the case, the admirable control of hemorrhage during the operation by means of a rubber band around the head is worthy of mention. The operation, which was performed by Dr. Buchanan, proved successful as far as recovery from the surgical procedure is concerned. The spasms still continue but are lessened in number.

Dr. B. Farquhar Curtis contributes a paper on

**Cases of Bone Implantation and Transplantation for Cyst of Tibia, Osteomyelitic Cavities, and Ununited Fractures.**

After reviewing the different methods and materials used for the purpose, the author concludes that Senn's decalcified bone appears for the present to be the most practical material for use in ordinary cases, while we are waiting for the ideal of the future—the insertion of a piece of living bone that will exactly fill the gap and will continue to live without absorption. The author reports four cases successfully treated by bone implantation. The most rigid antisepsis is necessary in the operation and the author cautions against the too free use of iodoform on account of the dangers of poisoning from it. Such an accident has not happened to him but the author thinks the caution necessary.

Dr. Judson Daland discusses

**The Treatment of Cholera by Hypodermoclysis and Enteroclysis.**

The treatment is principally of value in the evacuant or collapse stage of the disease. The solution used for hypodermoclysis consists of two small teaspoonsful of sodium chloride to a quart of hot water, which has been distilled and sterilized. The operation is one of great simplicity, requiring only a small-sized aspirating-needle and canula which is attached to the rubber tube of an ordinary fountain syringe. The best point for the introduction of the needle is in either flank, between the ribs and the crest of the ilium; the inner surface of the thighs may also be used. Observation has shown that there is danger in the injection of fluids in beneath the skin of the neck, as two cases of fatal œdema of the larynx following the operation have been reported. The operation should be performed under strict antisepsis. The first injection for an adult should be one or two quarts, and the solution should have a temperature of 110°F. at the reservoir which will be reduced to 105° F. after traversing the long tube to the subcutaneous space. The objection to enteroclysis that the injection will not pass the ileo-cæcal valve, the author believes to be without foundation. He reports that several patients to whom injections of tannic acid were given, vomited tannic acid, thus proving that the fluid passed the valve. The liquid for enteroclysis should also have a temperature of 110° F. which will be reduced about five degrees by its passage through the tube. Besides setting forth the value of the above procedures, the paper also deals with the general treatment of cholera.

**Puerperal Infection considered from a Bacteriological Point of View, with Special Reference to the Question of Auto-Infection**

is the title of a paper contributed by Dr. J. Whitridge Williams. After exhaustively reviewing the opinions of the observers of this subject, the author concludes that the general practitioner will do best for himself and his patient if he acts as if there were no such thing as auto-infection, and does not attempt to deal with any organisms which may exist in the vagina, aud contents himself with the most scrupulous cleanliness on his part and careful disinfection of the external genitals. The author also believes that it is impossible to disinfect the vagina with the means ordinarily at hand, and with the patient in her bed. This of course does not apply to well regulated hospitals, for there the douche may be given with greater antiseptic precautions. The best results will be obtained when, in addition to the most rigid subjective antisepsis, we consider each case separately, and make a preliminary microscopic examination of the vaginal secretion. If the secretion be normal there can be no possible justification for the use of the douche, but if pathological there may be.

Dr. Heneage Gibbes contributes a paper on "The Parasitic Nature of Cancer" in which he says that the most careful examination of specimens, hardened after a method which gave normal appearances in sections of normal liver, failed to show anything that could be construed into any form of parasite.

The remaining papers in this issue are: "A Suggested Improvement in the Correction of Lenses for Photomicrography, Photography, and Photastrography" by Dr. Henry G. Piffard, and "Simple Idiopathic Muscular Atrophy beginning in the Flexors of the Hips —Buzzard's Form" by Dr. Howell T. Pershing.

## MEDICINE.

### Differential Diagnosis of the Various Forms of Convulsions in Young Children.

Dr. Landon Carter Gray in discussing this subject before the New York Academy of Medicine, said that it involved the consideration of a large number of diseases, for a convulsion is a symptom, and not in itself a disease. A broad general classification of convulsions might be made into organic and functional. We know very little of cerebellar disease in the child, and our attention must be directed entirely to the cerebrum. In the organic class are the convulsions due to meningitis, encephalitis, meningo-encephalitis, and hydrocephalus. An organic lesion may be suspected when there is paralysis of some function of the cerebrum, as of sight or hearing. Cerebral hemorrhage may alone cause convulsions, and may be local or widespread. Organic lesions in the brain may cause convulsions, and may also impair mental power. Recently much has been said regarding the possibility of mental disturbance due to premature ossification of the bones of the skull. Lannelongue's operation has become a fad. It is useless, however, where there is distinct evidence of an organic lesion, as paralysis, blindness, or deafness. It can be of value only when the mental power alone is reduced.

A most interesting subject is that of functional convulsions. Chorea is sometimes mistaken for disorders of convulsive nature. Chorea appears under two forms. In the one the movements are fibrillary and very quick in their occurrence and beyond the control of the patient; in the other the motions are more gradual and wormlike. Experiments have recently been made regarding the convulsions due to digestive disturbance. It has been found that the normal putrefaction which always occurs during digestion sometimes becomes abnormal or irritative. In these cases the patient is slightly dyspeptic, and indican may be detected in the urine. These investigations are interesting and important, as they throw light upon facts which have long been known regarding the close association of digestive disorders and convulsions. Peripheral irritation has long been considered a cause of convulsions. There is no positive proof that ovarian disease ever of itself causes convulsions. Removal of the disorder is rarely followed by more than temporary relief. True epilepsy is masked by paroxysms which occur in series. This fact must be considered in discussing the disease, and in drawing conclusions regarding the treatment. No one can say at what period epilepsy is cured. The convulsions sometimes appear months or even years after a cure has apparently been effected.—*Med. Review.*

### Etiology of Whooping-Cough.

Dr. Ritter, of Berlin, has been making some researches into this subject. When it was possible to obtain any expectoration at the end of a paroxysm of coughing, the sputum was received into a sterilized vessel and carefully washed with distilled water. Small, opaque particles were generally found, and these were removed with due precautions and cultivated on agar-agar. Small colonies appeared within twenty-four hours. Under the microscope these were found to consist of diplococci. The colonies were opalescent and grayish in color, and adhered firmly to the surface of the cultivating medium. These diplococci are different from those described by Fraenkel as present in pneumonia. Although his experiments on animals were not yet completed at the time the report was made to the Berlin Medical Society, yet Dr. Ritter had already obtained results which seemed to point to this micro-organism as the specific agent in the production of pertussis. —*N. Y. Med. Record.*

## SURGERY.

### Surgery of the Gall-Bladder.

An excellent *resume* by Pick of Czerny's publication on the present status of this branch of surgical work merits attention. Czerny bases his conclusions on eighteen cases. He considers that cases without discomfort, even if the gall-bladder can be felt distended with calculi, should not be interfered with surgically. In these cases there may be short attacks of colic with jaundice; but they are readily relieved by medicinal treatment, and are not of frequent occurrence. The surgical cases are when the symptoms are severe, the attacks frequent, and the patient is not free from pain or discomfort during the remissions. The operative cases are classed either as those without long-continued icterus or with continued icterus. The cases without icterus often are difficult of diagnosis. Extirpation of the gall-bladder is not considered a desirable operation, since it does not prevent the recurrence of calculi in the dilated hepatic ducts; also, since the gall-bladder is valuable in forming a new outlet for the biliary current by its union (cholecysto-enterostomy) to the duodenum in cases when the common duct is occluded. In the non-icteric cases the surgeon has to deal mostly with the gall-bladder alone, since the ducts, except the cystic, are patent. The method of operating in two sittings is indicated when the contents of the bladder is purulent. The method used where the immediate incision is made is to pack the gall-bladder in iodoform gauze so as to shut off the abdominal cavity; then incise, and wash out with a boric-acid solution. The advantage of the open abdominal wound is that the

exterior and adjacent organs can be examined. When the bladder is opened after adhesions have formed, the interior of the bladder only is accessible, and the rest has to be left to nature.

An attempt at suture of the bladder wound and its replacement in the abdomen should never be done except when the bladder is in a normal condition.

In cases of suppuration or stenosis of the cystic duct the formation of a temporary fistula is recommended.

The typical operation for calculi is incision evacuation of calculi, suture of the gall-bladder, abdominal drainage for a short time. Extirpation is only indicated in severe or carcinomatous degeneration. When the common duct is occluded, operate as long as the patient's condition will permit. If the obstruction (stone or flexions) cannot be removed cholecysto-enterostomy is recommended. The incision recommended is a right-angular one, the vertical short arm in the linea alba. The horizontal arm immediately below the umbilicus and extending to the right. This, Czerny thinks, gives the best opportunity to investigate the ducts as well as the gall-bladder.

The risk to life is now less than for operations on the urinary bladder.—*Ann. of Surgery.*

## GYNECOLOGY.

### Danger of Vaginal Pessaries.

Dr. Neugebauer, of Warsaw, has published an exhaustive analytical monograph on this question, so important in these days when gynecology is widely practiced by the surgeon and physician as well as the specialist. Two hundred and forty-two cases of injury have been collected and analyzed, five more being added in an appendix. Tabulating the results, Dr. Neugebauer presents the medical public with the following formidable statistical records: Twenty-three cases of perforation of rectum alone by the pessary; twenty cases of perforation of the bladder alone; ten cases of perforation of the bladder and rectum; one case of ureteric fistula alone; one case of ureteric and vesico-vaginal fistula; one case of urethral-vaginal fistual; two cases of perforation of Douglas' pouch (neither fatal); three cases of perforation of the vaginal walls, the extruded portion of the pessary lying in the pelvic connective tissue; and six cases of entry of a vaginal pessary into the uterus.

As to the age, one patient was ninety years old; she had worn a wooden pessary forty-five years. The youngest was nineteen. The time during which the pessary was worn (and often forgotten) is tabulated, the nonagenarian just mentioned heading the list; two other women wore their pessaries for forty years; and twenty, besides these three, wore the instrument over twenty years. The toleration of the vagina is very varied in different individuals, even for the same kind of pessary; thus in some cases the pessary became fixed, and tended to ulcerate into the vaginal walls within two or three months, whilst in others the appliance was worn over twenty years without causing any objective or subjective troubles. How fetor could have been absent in these tolerant cases it is hard to understand. We must remember that the same kind of pessary is not always introduced with the same skill, whilst other pessaries may be bad in principle or ill-made by the manufacturer, and, lastly, the patient very frequently forgets that she wears a pessary, hence the share of blame which the introducer of the intrument should bear is not uniform.

When the patient is not aware that the instrument has been inserted, as is often the case, the medical attendant must undoubtedly have shown great skill and gentleness in introducing it, but he may not have taken sufficient pains to impress upon her memory the fact that the instrument has been introduced, and must not be worn for many months. This is the commonest cause of pessary accidents at the present time, for the art of introducing pessaries is readily acquired, experience is easily obtained, and the favorite pessaries are no longer barbarous instruments, whilst the patient may misunderstand such information as "I have passed a Hodge," or "You are wearing a Zwanck," and go away with the beleif that she is *not* wearing a pessary. As to the merits and disadvantages of the almost innumerable forms of pessary, we must refer the reader to Dr. Neugebauer's valuable paper. The moral is that the introduction of a vaginal pessary is a minor surgical proceeding, but if performed carelessly may lead to results in no sense "minor," but, on the contrary, very serious. —*Britsh Medical Journal.*

### The Sensitiveness of the Peritoneum.

Tait (*Lancet*, January 21, 1893) believes that the peritoneum is exquistely sensitive, as shown not only by the severe pain experienced by patients during a sudden internal hemorrhage, but by the agony which they suffer when it is necessary to open the abdominal cavity without anæsthesia. Moreover, he has frequently noticed that, on touching the peritoneum in women who were incompletely anæsthetized, reflex movements were frequently produced, indicative of the pain which was experienced. He addressed inquires to several different abdominal surgeons, many of whom expressed an opinion directly contary to his own. Sutton believes that while the healthy peritoneum is not especially sensitive, when inflamed it is highly so.

### Suturing the Ureters.

Trekaki (*Gaz. des Hopitaux*, 1892, No. 62) infers from experiments upon animals, as well as from the cases reported by Pozzi and Le Dentu, that patients do better when the proximal end of a wounded ureter is stitched into the abdominal wound than when it is turned into the rectum or vagina, since in the latter case infection may be carried to the renal pelvis, causing pyelitis.

He suggests that in cases of suppuration of the kidney, instead of extirpating the organ, it should be exposed by the usual lumbar incision, and the ureter drawn out and divided, after ligating the distal portion, the proximal end being stitched into the wound. This operation would be indicated in cases of inoperable pelvic tumors compressing the ureter, after traumatic rupture of the duct, and even in cases of severe cystitis, in order to protect the kidneys (?).

## NEWS AND MISCELLANY.

### A Valuable World's Fair Book.

The Passenger Department of the Baltimore and Ohio Railroad Company has prepared for general distribution a handsome pamphlet descriptive of the scenic and other attractive features of that road from New York to Chicago. This book should prove invaluable to those visiting the World's Fair. In its artistic cover, illustrations and reading matter, it is fully up to the high standard which has been fixed by the B. & O. for publications of this character. The scenery en route, which has gained for the B. & O. the richly deserved sobriquet of "Picturesque," the public buildings at Washington, old Harper's Ferry, Luray Cavern, and other attractive points are faithfully portrayed. The value of the publication is increased by descriptions and illustrations of the principal buildings at the World's Fair. This book can be procured free of charge upon personal application to ticket agents, B. & O. R. R. Co., or you can have it mailed to you by sending name and address with five cents in stamps to Chas. O. Scull, General Passenger Agent, Baltimore, Md. World's Fair tourists should bear in mind that the B. & O. is selling tickets at very low rates good going via Washington and returning via Niagara Falls.

### Deer Park and Oakland.

To those contemplating a trip to the mountains in search of health and pleasure, Deer Park, on the crest of the Allegheny Mountains, 3,000 feet above the sea level, offers such varied attractions as a delightful atmosphere during both day and night, pure water, smooth, winding roads through the mountains and valleys, and the most picturesque scenery in the Allegheny range. The hotel is equipped with adjuncts conducive to the entertainment, pleasure and comfort of its guests.

The surrounding grounds, as well as the hotel, are lighted with electricity. Six miles distant on the same mountain summit is Oakland, the twin resort of Deer Park, and equally as well equipped for the entertainment and accommodation of its guests. Both hotels are upon the main line of the Baltimore and Ohio Railroad, have the advantages of its splendid Vestibuled Limited Express trains between the East and West and are most desirable resting places for World's Fair tourists. Season Excursion tickets, good for return passage until October 31st, will be placed on sale at greatly reduction rates at all principal tickets officers thoroughout the country. One way tickets reading from St. Louis Louisville, Cincinnati, Columbus Chicago, and any point on B. & O. system to Washington Baltimore, Philadelphia, or New York, or vice versa, are good to stop off at either Deer Park or Oakland, and the time limit will be extended by agents at either resort upon application.

The season at these popular resorts commences June 15th.

For full information as to hotel rates, rooms, etc., address George D. DeShields, Manager, Deer Park, or Oakland, Garrett County, Maryland.

## ARMY AND NAVY.

U. S. ARMY FROM JUNE 25, 1893, TO JULY 1, 1893.

By direction of the President, Captain Marcus E. Taylor, Assistant Surgeon, will report in person to the president of the Army Retiring Board at Fort Logan, Col., when required by the board, for examination by it.

First Lieutenant Frank T. Meriwether, Assistant-Surgeon, U. S. Army, is relieved from duty at Madison Barracks, N.Y., and ordered to Fort Logan, Colorado, for duty.

Captain Louis A. La Garde, Assistant Surgeon, will, in addition to his present duties in connection with the World's Columbian Exposition, furnish the necessary medical attendance for the officers and enlisted men of the Army on duty at the Exposition grounds.

Captain William C. Shannon, Assistant Surgeon, in addition to his duties at the office of the Surgeon General, is assigned to duty as assistant to the Attending Surgeon in this city.

The leave of absence granted Major Washington Matthews, Surgeon U. S. Army, is extended one month.

Captain Freeman V. Walker, Assistant Surgeon, now on leave of absence at the Army and Navy Hospital, Hot Springs, Arkansas, will proceed at once to Fort Trumbull, Conn., and report at once to the commanding officer of that post for temporary duty, relieving Major Henry M. Cronkhite, Surgeon.

Major Cronkhite, upon being relieved by Captain Walker, will proceed to Fort Clark, Texas, and report in person to the commanding officer for duty at that post.

First Lieutenant Alexander N. Stark, Assistant Surgeon, is relieved from duty at Fort Monroe, Virginia, and ordered to Fort Clark, Texas, for duty; relieving Captain Edgar A. Mearns, Assistant Surgeon.

Captain Mearns, upon being thus relieved, will proceed to Nogales, Arizona, and report to the senior member of the commission appointed for the location and marking of the boundary between Mexico and the United States, for duty with the commission.

## WHY "MUMM" IS SO POPULAR WITH PHYSICIANS.

G. H. MUMM & CO.'S EXTRA DRY is recommended for its purity, its small amount of Alcohol, and its wholesomeness by such eminent physicians as:

**Dr. D. Hayes Agnew, Thos. G. Morton, Wm. H. Pancoast,** . . *PHILADELPHIA*
" **Fordyce Barker, Lewis A. Sayre, Wm. H. Thompson,** . *NEW YORK*
" **Alan P. Smith, H. P. C. Wilson,** . . . . . *BALTIMORE*
" **J. Mills Browne,** *Surgeon-General U. S. Navy;* **John B. Hamilton,** *Supervising Surgeon-General, Marine Hospital Service;* **Wm. A. Hammond, Nathan S. Lincoln,** . . . . . *WASHINGTON*
" **H. Byford, Chr. Fenger, R. Jackson, C. T. Parkes, E. Schmidt,** *CHICAGO*
" **A. C. Bernays, W. F. Kier, H. H. Mudd,** . . . . . *ST. LOUIS*
" **A. L. Carson, James T. Whittaker,** . . . . . *CINCINNATI*
" **Stanford E. C. Chaille, Joseph Jones, A. W. de Roaldes,** . *NEW ORLEANS*
" **C. B. Brigham, R. B. Cole, Levi C. Lane, J. Rosenstirn,** . . *SAN FRANCISCO*

"Having occasion to investigate the question of wholesome beverages, I have made a chemical analysis of the most prominent brands of Champagne. I find G. H. Mumm & Co.'s Extra Dry to contain, in a marked degree, less alcohol than the others. I therefore most cordially commend it, not only for its purity, but as the most wholesome of the Champagnes."—R. OGDEN DOREMUS, M. D., *Professor of Chemistry, Bellevue Hospital Medical College, New York.*

**NO OPENERS REQUIRED.** In using G. H. Mumm & Co.'s Extra Dry in sick rooms and families.

**CHAMPAGNE IMPORTATIONS.** Custom House statistics of 1892 show G. H. Mumm's Extra Dry to be 75,880 cases, being more than one-fifth of the entire champagne importations and over 9,000 cases more than of any other brand. It is noted for its excellence, purity and natural dryness.

G. H. Mumm & Co.'s Extra Dry of the excellent 1889 vintage is attracting great attention for its natural dryness, purity and quality.

### WHAT ARE THE INDICATIONS FOR REMOVAL OF THE UTERINE APPENDAGES?*

MARIE J. MERGLER, M. D., Chicago, Illinois.

The student who has an opportunity of listening to the opinion of half a dozen clinical teachers on the subject of indications for or against removal of uterine appendages in a given case, will often be surprised at their variance.

The patient who has suffered some time from dysmenorrhœa or from other pelvic pains, whether she seeks the advice of a number of the best general practitioners recommended to her at her home, whether she goes from one gynecological clinic to another, or whether she consults as many of the "best specialists" as her purse can afford, is often equally surprised at the variance of the verdicts. She will sometimes be undecided for months, and even for years, as to what course to pursue.

One has told her "try to allay the inflammation by local treatment and we can operate as a last resort." Another says: "Removal of the appendage is the only road to health; delay is hazardous; the risk of an operation nowadays is reduced to a minimum." A third doctor says, "you will probably never regain health without the operation, but on the other hand you must take your own chances in choosing a measure which endangers life, and even then we cannot guarantee success." If this patient follows the advice of the first, who said "Wait," she may be rewarded by perfect health, sometimes on account of judicious treatment and sometimes without any treatment whatever; on the other hand, possibly she and her friends may regret the delay if she suddenly succumbs to an acute septic pelvic peritonitis.

How about the patient who submits to the operation? She usually survives, frequently the ultimate result is all that has been promised; but almost every physician can recall some particular case or cases in which she is even worse than before.

I have in mind now one of these unfortunate ones who probably had consulted every gynecologist in this city, and who has tried to be admitted to the gynecological wards of several of our hospitals since her first operation. The ovaries had been removed for pelvic pain. She made a good recovery from the operation, but when she was able to be about the old pain returned with increased severity. For the vesical irritation of which she subsequently complained, the urethra had been dilated several times. One of the physicians treated her with electricity, but without success. Finally, removal of the uterus was suggested as a last resort. Whether she underwent this operation I do not know; but my impression of the case is that no surgical operation could bring relief to her, on the contrary any measure which would lower vitality would aggravate the trouble, for she was suffer-

*Read before the Illinois State Medical Association, 1893.

ing with a neurosis of central origin.

Those who have had a very large experience, and who have watched their patients for some years after the operation, will be able to select with considerable certainty the cases which may, or which may not be benefitted, but it is to be regretted that those who have their experience yet to gain, will find much in our literature that is contradictory and even misleading. I will except conditions in which the pathological changes are very conspicuous. On these there is no material difference of opinion; for instance, the reader will hardly be in doubt as to the propriety of removing ovarian tumors. The same applies to tubes which are considerably distended by fluid contents, or whose size is markedly increased by a neoplasm. Removal of the ovaries with the view of arresting the growth of some uterine fibroids is pretty generally sanctioned. The result in well selected cases is often most gratifying; the hemorrhage ceases and the tumor gradually shrinks.

So much for indications which are generally admitted. We come next to those which are the object of so much contention; indications which, when rightly apprehended, have been the means of inestimable benefit, but which, when misapprehended, have brought upon the sanguine operator the criticism of his brethren and the disappointment and sometimes the curse of his patient.

The indications just referred to are as follows: Inflammatory conditions of the ovaries or tubes, displaced and enlarged appendages, dysmenorrhœa, menorrhagia, epilepsy, hystero-epilepsy and various other neuroses.

My own observation has led me to conclude that the skepticism concerning operative gynecology in general and the utility of removing uterine appendages in particular, is not without foundation. After all that has been written in this country and abroad in favor of conservatism and against "too much surgery," the lessons are still too often left unheeded. For, on the one hand, claims of success are made in premature reports which do not stand the test of time; on the other, indications are imagined when they do not really exist. Those who assume the responsibility of deciding when it becomes necessary to remove the uterine appendages, may profit by a careful study of the writings of Doleris, Olshausen, Hegar, Lusk, Polk and others who have given this subject conscientious and careful consideration.

A thorough acquaintance with the works of standard authorities is one of the essentials to success; but even more essential than this is an accurate knowledge of the normal and pathological anatomy of the pelvis, and the acquisition of considerable skill in physical diagnosis. In the majority of cases where unnecessary operations have been advised, or where operations have been performed with very disappointing results, I believe it has been due to one of the following causes:

1. Too hasty decision to operate.
2. Mistaking functional disturbances of the appendages for primary lesions.
3. Mistaking hereditary taints and cerebral neuroses for the direct reflex of a local and acquired pelvic disease.

*Too Hasty Decision.* I recall at least a score of patients who have come to me from other physicians, on whom an operation had been urged as necessary, and who subsequently regained excellent health without it. One of these had been seen but once, examined hastily and told to go to one of our hospitals as soon as possible for removal of the ovaries. Very much worried, she went home, had a good cry and then concluded to see what another would advise. I had no knowledge of her previous experience when she consulted me. I diagnosed the case as endometritis with slight parametritis, and gave the patient a good promise as to recovery, but a guarded one as to time. I noticed at the time the patient asking rather anxiously "if her ovaries were not diseased" but failed to suspect a reason for anxiety. Her digestive function was very much disordered, she suffered with a severe headache, and her general nutrition was below par, as is usual in these cases. Six weeks of rest in bed, douches, careful dieting and tonics made a different woman of her. Her menstruation was painless, she could digest simple food and had gained in flesh; her headache was better but not entirely relieved. Suspecting eye strain, I sent her to an oculist, who fitted her with glasses which improved her head symptoms materially. This was two years ago; she is still in good health, and, when I saw her about a month ago, was pregnant.

Another case was one of well marked salpingitis and ovaritis. She had entered a hospital in a neighboring state and had made all preparations for removal of the appendages, but when the time of the operation arrived she lost courage and fled. As there was considerable swelling of the right tube, and she stated she had been a sufferer for many years, I told her frankly it was very doubtful if anything but an operation would help her, but if she was willing to put herself under treatment for six or eight months she might improve sufficiently to make an operation unnecessary. Nine months from that time she went home apparently well, and had continued to feel well for two years when last I heard from her.

Inflammatory conditions of the ovaries so frequently yield to judicious treatment that in every instance it should have a fair trial before the radical operation is urged. The same applies to inflamed tubes. Catarrhal inflammation of the mucosa of the tubes is usually simply an upward extension of an endometritis, and both may be self-limited. The infectious form is more obstinate and more likely to undermine the general health, and, indeed, often threatens life. But even in these cases if the conditions for drainage are favorable, recovery without removal is possible. Rest, antiphlogistics and drainage will often accomplish wonders. I admit that the cases of ovaritis and salpingitis due to infection, may at some time or other unexpectedly light up an acute pelvic peritonitis which proves fatal, yet this can hardly be regarded as an unqualified indication for immediate removal, for the number of actual deaths from that cause is very small in proportion to the number of appendages thus diseased.

The discomfort due to displaced ovaries is very frequently amenable to milder measures, especially where no firm adhesions exist. Neither displacement *per se*, nor enlargement of one or both ovaries are indications for removal. Both may be the natural consequence of a retroverted uterus, and all the bad symptoms and the enlargement will subside as soon as that organ is replaced and kept in position. Marked ovarian enlargement, associated with grave local and reflex disturbances, may be very transient. It is usually due to venous stasis and is particularly noticeable just before the menstrual period.

The following was to me an instructive case some years ago. I was called to the country to see a patient and her daughter. The latter was lying in bed suffering with severe pelvic pains. The mother stated that the girl, who was fourteen years old had never been well; that she had menstruated for the first time six months previous, and since that time had paroxysms of severe pelvic pain associated with great mental depression. The girl seemed very anemic and not well developed physically, and had been subject to constiption. On making a pelvic examination I found a small retroverted uterus, and the right ovary of the size of a large hen's egg, prolapsed and very tender. The uterus could be easily replaced. The ovary was so large and resistant that I took it to be a small dermoid, but requested the patient to call at my office in a few weeks for a second examination. In the meantime I prescribed iron and laxatives. When she presented herself a month later, the ovary was normal in size and the pelvis free from pain. The patient had menstruated soon after my first visit. The enlargement in this case must have been due to the displacement and premenstrual congestion.

*Mistaking Functional Disturbances Due to Other Causes for Primary Disease of the Ovaries aud Tubes.*—Women whose general nutrition is disturbed, or those who are subject to great nerve strains, and those who are overworked and underfed are very likely to suffer from dysmenorrhœa. Strict attention to diet, change of occupation and rest are indicated in these cases, and will often remove the difficulty without any local treatment whatever.

I have known functional disturbances, particularly dysmenorrhœa and menorrhagia due to the lithic diathesis or constipation, to be mistaken for chronic ovaritis.

Hastening the menopause by removal of the appendages would hardly be the most scientific treatment in these cases.

*Mistaking Hereditary Taints and Central Neuroses for the Direct Reflex of a Local and Acquired Pelvic Disease.* The removal of the ovaries and tubes has been practiced successfully for severe forms of epilepsy, hystero-epilepsy and different forms of psychoses; but it is very essential before considering this measure in a given case, to determine whether these neuroses

are really reflexes of genital origin, or whether our patient is haunted by the ghosts of a neurotic ancestry. Should the latter be the case, the removal of the ovaries will aggravate the neuropathic tendency.

Some authorities claim that this operation is only justifiable where we can demonstrate the presence of ovarian disease by physical examination. Other equally good authorities claim that, since grave psychical and other reflex disturbances do occur in cases where the seat of the lesion could not be previously determined, the operation is in some of these cases justifiable, since the field for this operative interference is still to be determined to some extent in an experimental way. This belief, however expressed by men of large experience who have given the subject careful study in all its phases, offers no excuse for hasty decision, without acquainting patients and their friends of the comparative uncertainty as to the results in this particular class of cases. Nor does it justify the proceeding to the removal of organs about whose size, form and position the advisor does not even pretend to have any definite knowledge. This I have known to be done. Unfortunately, it is much easier to acquire the technique of the operation than the judgment of when to operate.

In conclusion, up to the present time the experience of our best authorities would define the legitimate limits of the operation as follows :

1. Existence of neoplasms in the appendages.

2. Hernia or prolapse of the ovary, when irreducible and when producing urgent symptoms which do not yield to palliative treatment.

3. To the arrest of the growth of uterine fibroids. Here the limits can hardly be said to be definitely fixed. As a rule, however, the operation may be taken into consideration for tumors which are submucous or interstitial, before the uterus has attained a great size (Olshausen puts it at the size of a four months pregnancy). It may also be considered in fibroids when the symptoms are urgent and when either on account of cardiac weakness or from the presence of nephritis, so common in fibroids, the more radical though more dangerous, operation of laparo-hysterectomy would be attended with too much risk.

4. Inflamed conditions of the appendages, whose symptoms render the patient's life a burden, and which have resisted a fair trial of palliative treatment. These conditions when complicated by extensive adhesions of the organs, are less likely to yield to mild measures. Even in these cases the breaking up of firm adhesions, after abdominal section without removal of the ovaries and tubes, has been followed by relief of the symptoms.

5. The presence of pus in the ovary and encysted pus in the tube, as a rule require the radical treatment.

6. Marked reflex neuroses whose origin may be traced directly to diseases of the appendages.

These indications can be but general guides; an inflexible rule cannot be laid down. Every case must be studied by itself and at all times removal should be regarded as the last resort.

---

### A Slight Mistake.

An instance where a bad cold caused a startling conversation.

There is a joke being told here at the expense of a modest young newspaper man in a neighboring town which is so good it ought to be true, says the *Bristol News*. The young man in question, it appears, was recently invited to a party at a residence where the home had recently been blessed with an addition to the family. Accompanied by his best girl he met his kind hostess at the door, and after customary salutations asked after the welfare of the baby. The lady was suffering from a severe cold, which made her slightly deaf, and she mistakenly supposed that the young man was inquiring about her cold. She replied that though she usually had one every winter this was the worst she had ever had; it kept her awake at night a good deal at first and confined her to her bed. Then noticing that the scribe was becoming pale and nervous, she said that she could see by his looks that he was going to have one just like her's and asked him if he wished to lie down.

The paper came out as usual the next week, but the editor has given up inquiring about babies.

# CLINICAL LECTURES.

## RECURRENT CANCER, TALIPES, ABSCESS OF NECK, CRANIOTOMY.

ROSWELL PARK,* A. M., M. D.

I am about to show you a case of disappointment, not to me but to the patient, who came here yesterday from a distance for the purpose of submitting to operation for recurrent cancer of the breast. The trouble was first noticed last January; on March 26, the entire left breast was removed and in May, pain began to be felt in the arm as if there were rheumatism. At the present time, ten months after the inception of the disease, there is great limitation of motion in the left arm. You can see the scar of the operation on the chest, but I find no scar in the axilla where I should like to, because I make it a rule always to clean out the axilla in a case of malignant disease of the breast whether involvement of the lymph-nodes is apparent or not. The disease has evidently extended to the tissues about the brachial plexus and I have told the patient that any operation that would be efficient, would probably be fatal because there is so much to be removed. Disarticulation at the shoulder—as recommended by Esmarch—would be necessary and even this would probably not eradicate the disease. There is no history of hereditary predisposition to malignant disease except that a maternal aunt died of what was in all probability cancer.

The case not being operable, I have suggested inoculation with erysipelas, a procedure which has been found to be followed with beneficial results.

---

This child, eighteen months of age, has a mild club-foot which requires a severing first of the tendo Achillis, because the toes can not be drawn up, and then of the plantar fascias or possibly of one or two flexor tendons, in order to overcome the excessive arching of the foot. There is also some tendency to inversion but the main trouble to relieve is the shortness of the tendo Achillis. You can readily supply the technical name of the deformity—talipes equino-varus.

After performing tenotomy I find that the foot can be brought up in flexion but the tightness of the plantar fascia still requires relief and I now divide that structure subcutaneously, passing the knife outward through a small opening at the inner side of the arch of the foot. The foot can now be restored to its normal position and I shall dress it with a starch bandage. You notice that even now, although the foot can readily be placed in the normal position, the inner tendons pull it back into the old deformity just as a horse's head is pulled to one side by a bridal rein. After the wounds have healed, it will be necessary to resort to massage and electricity, applied to the peronei so as to tighten the loose bridle rein and bring the foot around.

---

Seven months ago I operated on this young woman, who had been walking on the external malleolus on account of a bad form of club-foot. Over the malleolus had developed a large bursa—an instance of a cyst of new formation serving a conservative purpose. The sole was turned up against the other foot. The operation of astragalectomy was made as aseptically as possible and the limb was done up in a plaster dressing. There is still a little soreness of the foot when the patient walks too much but otherwise she has no trouble. You notice that the foot is shorter than the other. This is not due to the operative interference but to previous failure to develope from non-use. The shoe worn is like that on the other foot except that the heel is raised a trifle to compensate for the shortening of this limb. If I had done an ordinary tenotomy here and then relied on a club foot shoe to correct the deformity, the same result would have been attained after two or three years. In as many months she

*Prof. of Surgery University of Buffalo; Surgeon to Buffalo General Hospital.

has as good a foot from the severer measure of removing one of the tarsal bones in order to straighten the foot. It is a result such as this that justifies the more radical operation. The patient has not yet recovered by any means as much use of the foot as she will later, for she is old enough to aid the surgeon by intelligent co-operation. In the little child on whom I did a tarsectomy four weeks ago, the starch dressing was left on two weeks and a half and then replaced by a plaster bandage. After that is removed, it will be necessary to keep on a club-foot shoe for some months as the child can not be relied upon to make the voluntary effort to roll the foot outward and to "toe out."

"As the twig is bent, the tree is inclined" and, in applying this old maxim to orthopædic surgery, we must bear in mind the necessity of maintaining the corrective impression night and day. In the case of the little child, direction must be given to the parents to keep the club-foot shoe on continually except as it is occasionally removed for a few minutes to allow massage or for purposes of cleanliness.

---

This child, eighteen months old, has been brought here with a swelling in the neck which has enlarged rapidly in the last few days. On examination I find fluctuation and presume that the case is one of acute inflammation of some of the cervical lymph nodes. When such a case presents itself to you and there is no ostensible reason for the enlargement, I would advise you to examine the teeth, the tonsils and the ears to see if there is any septic process which may account for involvement of the adjacent nodes. Failing to find an explanation from this examination it would be well to turn your attention to the scalp, for eczema of this region may be accompanied by inflammation of the lymph nodes. The tonsils are like sponges, having crypts which retain infectious debris,and there may follow systemic symptoms from the absorption of this material. Such absorption takes place through the lymph vessels to which the lymph nodes bear the relation of filters. It is in the nodes, therefore, that septic material is retained and suppuration is set up. If the infectious material is tubercular, a tuberculosis of the lymph nodes results which has been called scrofula.

Now in such an inflammatory tumor as this, with fluctuation and the tenderness which was manifest before the child was anæsthetised, we can be confident that we have an abscess and I do not think it would be a mistake to make free incision into it. But in order to demonstrate absolutely that the tumor is not an aneurism or a soft mass not containing pus, I will follow for your benefit the absolutely safe method of first introducing a fine needle connected with a syringe by means of which pus is removed. The indication for free drainage is clear. You will notice that the field of operation is rendered aseptic before the knife is used. This may not be necessary since we expect to have it flooded with infectious matter, but few patients who are brought to a hospital are injured by the application of water, the use of the antiseptic solution causes only a moments delay, and we can be sure that, if further signs of sepsis develop, they are due to internal sources and not to any germs that we have introduced. This abscess seems quite extensive and I may have to scrape it out, so that an incision at least an inch long will be necessary. I shall follow one of the creases in the skin so that the scar may not show after it has healed. You might say that in cutting transversely I am in greater danger of dividing vessels, but the abscess is immediately below the superficial fascia and there are no large vessels to be encountered. My finger goes into a cavity the size of a robin's egg after a considerable quantity of pus has been evacuated. The walls of the cavity are thick and tough but do not require so much scraping as I had anticipated. The cavity is washed out with a hydrogen peroxide solution.

On examining the child I have found nothing wrong in the mouth or throat and the ears and scalp are apparently healthy. There must be an underlying cause for every abscess, but I discover none here. Alterative tonics will be administered, the wound will be dressed daily with a little tent of iodoform gauze to prevent the adhesion of the fresh raw edges until the cavity beneath has closed by granulation.

---

This patient is a little imbecile child on whom I purpose to perform the operation of craniotomy. The word *craniotomy* in

this connection has not its obstetrical meaning, but is used in the literal significance of cutting the cranium. The object of the operation is to divide the skull in such a way as to enlarge its capacity and allow the brain to expand. The term craniectomy has been more recently applied to this operation, but as we cut *out* nothing but the narrow strip of bone that corresponds to the width of the saw, I think that craniotomy is the preferable term. The operation consists typically in making a linear, longitudinal opening in the skull as near the middle line as is possible without wounding the superior longitudinal sinus. The opening I prefer to make on the left side, because it is on that side that the centres of speech and those governing the movements of the right side of the body are located. In the present case I expect to do more than the usual operation, intending to extend the incision in a semicircle or horse-shoe, and spring up quite an area of the side of the skull. This lid or operculum will not be cut loose from its vascular connections, for the soft parts will remain attached to it, and as the bone itself is not broken entirely loose, there will remain a hinge or bridge containing an abundant supply of blood vessels to supply nutrition. You have recently seen another case of craniotomy in which a Y-shaped incision was made, and you know that, whatever the manner of separating the skull, the object of the operation is to afford a relief from intracranial pressure.

We have had great difficulty in shaving this child's head, for he would not keep still. Except during sleep, most of his time is spent in jumping up and down on his hands and knees in his crib, playing a kind of idiotic leapfrog with himself. It has been noticed that the child's radial pulse is good on one side and scarcely distinguishable on the other, so that there must be some anatomical anomaly.

Under chloroform anæsthesia, the head is shaved and then cleansed with a mixture of turpentine, alcohol and ether to remove the sebaceous matter. The field of operation is now irrigated with a bichloride solution and the head bound by an Esmarch ligature to prevent loss of blood as far as possible. Towels wrung out of a bichloride solution are used to protect the shaved scalp from the encroachment of septic germs from the face and neck. The operation will proceed under ether anæsthesia.

The first incision is in the form of a semicircle, seven cm. in diameter, about the left parietal eminence. If I were making an ordinary trephining, I should now dissect up this semicircular flap; but, as its vascular connection with the bone must be maintained, access to the skull is obtained by dissecting away the scalp to the outer side of the incision, and, for the sake of greater freedom, a connecting incision, extending straight backward, is made. With the DeVilbis saw a groove is marked in the bone. I shall work with chisel and bone-punch in this groove. It is a term of reproach to call an individual thick-headed, but the epithet seems to have an anatomical justification, for almost every idiot on whom I have operated has had an abnormally thick skull. In order to be able to handle the tools intelligently, I am going to learn the exact thickness of bone in this case by means of the trephine. The small button of bone which is removed measures 5 mm., quite an ambitious thickness for a boy of six. Into a skull of this thickness and density the saw would penetrate about as quickly as it would into a piece of marble. It is, therefore, practically useless except to outline the work for the other instruments, and, though I have no great liking for the chisel, it will be necessary to use it in this case. As the bone is penetrated, iodoform gauze is stuffed into the wound to exclude septic material and to prevent oozing from the bone.

I have now succeeded in cutting through the entire length of the groove and the horse-shoe shaped trap-door is pried up with a lever. With the closely approximated poles of a faradic battery, I am trying to produce a muscular response to the excitation of the mother centers in the cerebral cortex. Ordinarily this can be done through the dura mater, but in this case there is no response. There is considerable tension of the dura and I shall divide it parallel to the course of the majority of vessels which are visible, so as to avoid hemorrhage as much as possible. I can get no response to the electrical stimulus, even when nothing but the pia and arachnoid intervenes. The tension of the brain is very evident from the way in which it protrudes through the opening in

the dura. Although the pressure has been relieved over this area, it is hopeless to expect a skull as thick as many an adults' to expand sufficiently to allow the proper development of the entire brain. The antipyrin spray (5 per cent.) is used to control hemorrhage and the dura is closed with fine cat-gut. The lid of bone is laid in place and the scalp wound sutured with cat-gut and dressed antiseptically. It will probably be necessary to keep the child's hands lashed in order to prevent him from tearing off the dressings. The immediate prognosis is favorable, the pulse is better now than it was when the child entered the hospital and there is no reason to anticipate any trouble from the surgical interference. We can hope for a slight mental improvement and even that will be an important gain, but the prognosis, so far as perfect mentality is concerned, is decidedly unfavorable.

# COMMUNICATIONS.

## THE PRESENT POSITION OF THE HYPODERMIC METHOD IN THE TREATMENT OF SYPHILIS.*

J. WM. WHITE, M.D., Philadelphia.

While the use of hypodermatic injection in syphilis dates back nearly thirty years, the alleged superiority of this method of treatment to all others has been most persistently set forth by its advocates during the last ten years. Their arguments are based primarily upon the shortcomings of the methods of mouth ingestion and inunction, and further upon certain alleged advantages claimed for the hypodermatic method itself.

The specific claims made by those who have been exploiting the method are as follows (Sukhoff, Damman, Elsenberg, Lang, Blazer, Lewin):

1. The practitioner remains "master of the situation" throughout. This is one of the glittering rhetorical generalities indulged in occasionally by our Continental colleagues, which may mean anything or nothing, and to which a definite reply is always difficult. In this instance, under the most limited interpretation possible, it is not warranted by the facts.

2. The drugs needed may be easily obtained in the pure state. This is not peculiar to the hypodermatic method.

3. They may be prepared for use by the physician himself. This, if ever an advantage, is scarcely worth mention.

4. In the use of the soluble salts of mercury a precise dosage is obtainable. It may be safely asserted that the varying degrees of local reaction affecting the rapidity and the thoroughness of absorption do not give rise to as much variation in the dose as do the differences in absorptive power in the skin and the gastro-intestinal mucous membrane.

5. It saves time and labor on the part of both physician and patient, rendering visits more infrequent, etc. This is doubtful, and not very important, if true.

6. It necessitates but little alteration in diet, habits of life, etc. Such alteration, under ordinary methods, is practically only that indicated by the general rules of hygiene, and would be beneficial to most persons, non-syphilitics included.

7. The patient's skin and digestive organs remain unaffected, except in rare instances. This is true, but is offset by the pain, the liability to abscess, and other objections to be described later.

8. Stomatitis is of rare occurrence. This is not correct. The evidence goes to show that with equal care it is more likely to occur during hypodermatic medication, and when it does occur comes on more suddenly and is more intense and uncontrollable than under either of the other methods.

9. It enables the patient to conceal the disease. This may have some little force when the method is compared with the inunction treatment, but is certainly a very minor point in any event.

* Abstract from Transactions of Philadelphia County Medical Society.

10. It lessens expense. This is likewise of little importance, as the difference is not great.

11. It is more likely to affect an entire and permanent cure, and does so in the shortest time and with the minimum amount of mercury. This is, after all, the most important claim that is made, and if it could be established would warrant the adoption of the method to the exclusion of all others. I am of the opinion, however, that it cannot be substantiated, and at any rate am certain that the time has not yet arrived for a final and judicial decision upon the matter. The evidence is contradictory, and is open to the suspicion of bias upon both sides, but especially and notably upon that of the advocates of hypodermatics.

12. In the presence of grave and imminently threatening visceral troubles it affords the readiest and surest way of producing a powerful influence. This may possibly be admitted, although in the great majority of cases there is ample time for the employment of inunctions.

13. In doubtful cases it shortens the time required for the "therapeutic diagnosis." This is scarcely to be included among the advantages belonging to a system intended for routine treatment. It is especially claimed for the hypodermatic use of calomel, and will be discussed in connection with that drug.

The objections to the method may be more briefly mentioned, as I believe they are all well founded.

1. It is painful, and in many patients excites apprehension, and is strongly objected to. It might be added that the measures advocated to obviate or lessen pain, viz., the precedent or simultaneous administration of morphine or cocaine, are in themselves highly objectionable, and certainly to be discouraged.

2. It is occasionally, though rarely, dangerous, and sometimes rapidly fatal. This is undoubted.

3. It is liable to be followed by certain local complications, which are: (*a*) erythema; (*b*) painful nodosities; (*c*) cellulitis; (*d*) abscess; (*e*) sloughing.

While the percentage of these troubles is small in the reported cases, it must be remembered that the bulk of the enormous mass of literature referring to it which has accumulated during the last decade has been contributed by partisans. This prevents me from being much influenced by figures showing, for example, that "in 36,922 injections in 3185 patients, suppuration occurred in 116, or less than one-third of one per cent." (Damman: *Aust. Med. Jour.*, March 15, 1892).

4. It cannot be properly carried on by the patient, but always requires the intervention of the surgeon. In attempting to review the contributions to this department of syphilology I shall not attempt completeness, both because of lack of space and for the reason that so much that has been written is, if not stale and flat, certainly weary and unprofitable.

The chief subdivisions of the hypodermatic method are based upon the solubility or insolubility of the mercurial preparations which are employed, the leading member of each group being respectively the corrosive chloride and the mild chloride.

The technique of their introduction is practically identical in both classes.

(*a.*) The solution or emulsion used should be sterilized.

(*b.*) The skin of the region selected for the puncture should be cleansed with soap and water, then with alcohol or turpentine, then with a 1 to 20 carbolic solution, and finally with 1 to 1000 sublimate solution. The hands of the operator should be similarly prepared.

(*c.*) The needle, which should be larger and longer than the ordinary hypodermatic needle, and the syringe itself, should be washed in 1 to 20 carbolic solution for at least fifteen minutes before using.

Any form of syringe may be employed, the essentials being that it is capable of complete sterilization, works easily and smoothly, and holds the necessary quantity of fluid. For some of the preparations employed a rubber syringe and a silver or gold needle are of advantage. For many of them the ordinary hypodermatic syringe, with the larger needle, will suffice.

Much has been written about the site of injection and its depth. There seems reason to believe that the local influence of mercury is of great advantage, and the existence of a serious lesion at an accessible locality may occasionally determine the point of injection. Usually, however, the post-trochanteric region has been chosen as one which is not subject to pres-

sure or to the observation of others, and which is not especially sensative. The statement has been made (Taylor, *op. cit.*) that experience shows the thighs to be particularly liable to undergo suppuration, and that they should therefore be avoided. The same advice is given as to the arms and forearms. The only *a priori* reason which occurs to me in explanation is that the constant use and motion of these parts may favor inflammatory changes. They would naturally be selected frequently under ordinary circumstances for hypodermatic medication, and the fact of their special susceptibility to abscess ought to be fully demonstrated before they are excluded from the list of available sites. The regions where the skin is closely applied to bones, those where cellular tissue is scanty and those subjected to pressure in ordinary positions should be carefully avoided, as should those in which suppuration or sloughing would be followed by noticeable disfigurement. As to the depth at which the injection should be deposited, the choice lies between the muscular tissues and the subcutaneous connective tissue. In my judgment the preference should undoubtedly be given the latter, as if abscess occurs it is much more easily managed than if it is subfascial.

The method of throwing in the fluid is identical with that of giving an ordinary hypodermatic injection. A fold of skin should be pinched up and the needle introduced parallel to its long axis and to the required depth. The point of puncture should be covered with the finger of the operator as the needle is withdrawn, and then sealed with a little iodoform in collodion.

All these precautions cannot prevent occasional microbic infection from the deeper layers of the skin, and unless the fluid used happens in itself to be antiseptic, this accident will be followed by cellulitis or abscess.

We may consider the special substances used in the two great groups.

### I. THE SOLUBLE SALTS USED HYPODERMATICALLY.

(*a*). Corrosive sublimate.—The dose is from $\frac{1}{12}$ to $\frac{1}{4}$ of a grain dissolved in about 20 drops of distilled water. It may be given in an average case every second or third day until stomatitis is threatened, and may then be used at longer intervals. If selected on account of some emergency, larger or more frequent doses may be employed.

(*b*). Asparagin: Mercury.—Two and a half drachms of asparagin is dissolved in warm water, and oxide of mercury added to saturation. The solution is filtered after cooling, and the amount of mercury estimated. It is then diluted to make a 1 or 2 per cent. solution of mercury as required.

(*c*). Succinimide of mercury, used in a 5 per cent. aqueous solution in doses of $\frac{1}{60}$ to $\frac{1}{20}$ of a grain.

(*d*). The oxycyanide has been used by Bœr in 1 gramme (15 grains) injections, containing 1.25 per cent. of the mercurial.

(*e*). Mercuric Albuminate. — An unstable compound of white of egg, sodium chloride and sublimate; of indefinite composition and liable to rapid deterioration.

(*f*). The Iodo-tannate of mercury (Nouny) may be used in the following formula:

℞
Hydrargyri..... gr. 1-16
Iodini..... gr. ¼
Acid. tannic..... gr. 3-10
Glycerine..... gtt. xv
M.

(*g*). Carbolate of mercury has been used by various experimenters in doses of $\frac{1}{6}$ to $\frac{1}{3}$ grain dissolved in 15 drops of water.

(*h*). The formamide of mercury.

(*i*). Alaninate of mercury.

(*j*). The benzoate of mercury is preferred by Balzar and Thiroloix (*La Méd. Moderne*) who say: "this salt coagulates albumen far less than other combinations of mercury, and hence it exercises a less energetic action upon the cutaneous nerve-filaments. It does not seem to cause gastro-intestinal complications or abscesses, and no case of gingivitis ever went on to marked salivation. The injections may be practiced in any part of the body, but are less painful in the back. The objections to this salt are that many injections are required, that it deteriorates on keeping, and that it sometimes causes induration at the point of application. Cochery (*Thèse de Paris*, 1890) says that the fact that the benzoate does not coagulate albumin is the explanation of its comparative painlessness. He found that this, like other preparations, is not well borne by very stout persons, the presence in the connective tissue spaces of masses of fat preventing the

satisfactory diffusion of the remedy. The same observations have been made by others. Brousse, of Montpelier, prefers this salt to all the other soluble preparations.

II.—THE INSOLUBLE SALTS USED HYPODERMATICALLY.

(*a*). Calomel, which may be taken as the type of the insoluble preparations, may be used in the dose of one-half to one grain every four days, two grains weekly, or three grains every ten or twelve days. It may be given in one of the following mixtures:

℞ Hydrarg. chlorid. mit..... gr. ½.
Glycerinae purificat..... gtt. x.
Aquæ destillat..... gtt. x.
M.

℞ Hydrarg. chlorid. mit..... gr. j.
Mucilag. acaciae..... gtt. xx.
M.

℞ Hydrarg. chlorid mit. } ..... āā gr. j.
Sodii chloridi }
Aquae destillat..... gtt. xxx.
M.

The calomel used should be sublimated by steam and perfectly sterile.

The method in use by Besnier at the Hôpital Saint Louis may be taken as the type, and is, therefore, given in detail: The formula used is calomel, 1 part, oil of vaseline, 20 parts. The calomel is incorporated with the petro-vaseline and well shaken, to put the insoluble substance in as perfect suspension as possible, and the mixture is then boiled a few seconds before making the injection, in order to sterilize it. The operator should wash the hands in a mixture of alcohol and liquor of Van Swieten, and cleanse the part where the injection is to be made with some absorbent cotton wet with the same solution. The needle of the syringe should be cleansed. The choice of location for making the injection is a point of the buttocks, about three centimeters below the crest of the ilium and an equal distance above and to the inner side of the great trochanter. The mass of muscles in this region are favorable for the injection, and they do not support the weight of the body in sitting. The skin is displaced somewhat, so that there is no direct continuation of the puncture of the integument and that of the deeper tissues. The insertion of the needle is done quickly at one stroke down to the guard. By operating in this way the patient scarcely feels its introduction. The injection is then made gently, but a certain force must be employed to secure a passage of the emulsion into the tissues.

The employment of calomel subcutaneously was originally advocated by Scarenzio in 1864, but was not very extensively used, except in Italy and Germany until the writings of Smirnoff in 1883 and 1886 called renewed attention to it.

During the interval, Sigmund was the most prominent syphilographer who carefully investigated the claims which were made for it, reaching the conclusion that we cannot hope to "cure" syphilis by a few injections of this or any other salt of mercury. Since then it has been used very largely, and its limits of usefulness as well as its dangers are now fairly well understood.

We may consider the latter first.

Locally, there is almost always pain of greater or less severity.

There is almost always an inflammatory reaction, which, when slightly developed, causes merely a flush around the needle puncture,and a feeling of heat or itching. Lasser has reported a case of extensive mercurial erythema. Oftener there is an exudation of lymph with the formation of a hard, horny nodule, moderately tender to the touch and very painful if subjected to continuous pressure. This is usually absorbed if asepsis has been good, but in a certain proportion of cases goes on to softening, to suppuration and to the formation of an abscess. It rarely or never disappears under two weeks, often persists for a longer time, as has been shown by Balzer at autopsies, and its disintegration is sometimes attended with extensive sloughing and cellulitis.

Constitutionally, calomel injections have produced the following unfavorable results. Stomatitis, in spite of the assertions to the contrary, has not been infrequent, is often very persistent, and is sometimes of a very grave variety, attended with all the more dangerous phenomena of ptyalism. It is the more serious, as it comes on suddenly (fulminating type), and is very rebellious to ordinary treatment. This intractability is probably due to the continuous absorption going on from the point of deposit of the drug, and has in more than one instance neccessitated the excision of the indurated tissue thereabouts (Volger has reported three such cases), and the cauterization of the walls of the resulting wound. Gastro-enteritis and colitis have

occurred (Besnier) and have even been fatal (Kraus), and two cases of pneumonia following a calomel and oil injection have been reported (Klotz), and were presumably due to oil embolism.

On the other hand, the influence of the drug thus used upon the symptoms of syphilis in the secondary stage, and its occasional value as an adjuvant to the iodides in the treatment of later phenomena when grave or dangerous, have been abundantly demonstrated. The most striking results have been obtained in specific eye troubles, but various forms of visual and connective tissue lesions have been reported as rapidly cured by its use.

There can be no reason to doubt its efficacy (if properly administered) during the secondary stage of syphilis. Mercurialization, however produced, is then at its acme of usefulness. There is much more reason to question the reported benefits in all forms of tertiary syphilis. It is contrary to the accumulated experience of the profession to find, in late syphilis, that gummata, periosteal nodes, osteitis, tubercular syphilides and other phenomena of similar character yield promptly to the use of mercury alone. It is undoubtedly of value then as an adjuvant to or in conjunction with the iodides, but on both theoretical and clinical grounds cannot be expected to supersede them.

Smirnoff's reported cases require confirmation. Taylor acutely says: "Smirnoff significantly remarks that if, during a course of injections in tertiary syphilis, aggravation of the symptoms occurs, they should be stopped at once and the iodide of potassium should be substituted."

One possible advantage of calomel may be properly mentioned here. Jullien (*Le Bulletin Medical*, June 19, 1892), calls attention to its diagnostic value in doubtful surgical cases: He says: "The propriety of operating in certain cases is, in the experience of every surgeon, counteracted by uncertainty of diagnosis; an ulceration, a tumor of ambiguous identity, makes one suspect cancer, without casting aside all waverings toward the side of syphilis. The surgeon should, in such a case, institute a course of treatment to throw light as rapidly as possible on the obscure points. Under these conditions, Jullien says he cannot too vehemently proclaim the superiority of calomel injections used according to the Scarenzio-Smirnoff method: $\frac{1}{12}$ grain (0.097 gramme) of calomel suspended in 15 grains (0.97 gramme) of liquid vaselin, thoroughly sterilized, and injected once into the gluteal muscles under aseptic conditions. He says no one can deny the profound modification which it exercises upon a syphilitic neoplasm, no matter what has been its duration. In five cases which he cites he determined whether a tumor was a manifestation of syphilis or not, in short, whether or not operation was indicated. He adds:

"Calomel by injection presents, in the highest degree, the qualificatious of a test-medicine." He thinks that no argument can be brought up in opposition; and that if the surgeon does not utilize this method, "it is not—it cannot be—that he condemns it, but that he is ignorant of it." It may be discarded in the methodic, prolonged treatment of syphilis; but all its inconveniences are obliterated by two indubitable facts in the presence of doubts concerning a malignant degeneration, where "delays are dangerous." These two facts are: "1. That a therapeutic diagnosis of syphilis is clearly defined in eight days by injection of calomel. 2. In case of negative results, this treatment has not impeded the necessary operation in the slightest degree, and does not in the least complicate its results." However, even Jullien says that it must not be used blindly, and that it is best not to employ it in cases of marked albuminuria. If further experience confirms these observations, it will be one of the best practical results following the excessive (and unnecessary) use of hypodermatic treatment which has been the fashion for some years on certain parts of the Continent.

(*b.*) Metallic Mercury. The dose employed has been from 5 to 20 or 30 grains once weekly, followed by kneading and rubbing of the region.

(*c.*) Gray Oil (*Oleum cinerium*) is a form of metallic mercury which has been much more widely used. It is prepared by making an ointment or pomade of mercury with lanoline as a basis, and then diluting this with almond or olive oil (Lang), or by triturating metallic mercury with etheral tincture of benzoin and oil of vaseline (Neisser), or by combining with the mercury and lanoline a two per cent. carbolized olive oil (Althaus).

(*d*). The yellow Oxide of Mercury. Taylor says that this salt is to-day the most generally used hypodermatically of all the mercurial compounds, having largely replaced calomel. The evidence as to their comparative value is not so conflicting as usual. The drug was introduced by Watrasewski, who gave up calomel on account of the pain and unpleasant symptoms which it produces. His formula is :

℞ Hydrarg. oxid. flav..... gr. xv
Acaciae..... gr. iv
Aquae destillat..... f ʒi.—M.

He uses a Pravaz syringeful, and says that three to six injections suffice for a "cure," which Taylor says, "it must always be remembered, means, in the minds of most exploiters of hypodermatic mercurial preparations in syphilis, the disappearance of a given set of symptoms or lesions." The following remarks of Taylor throw such a strong side light on this whole question of the hyodermatic treatment of syphilis that I quote them fully : "Tchernoguboff uses this preparation in doses of 2 grains every ten or eleven days, injected into the muscles. He says that syphilitic children from 12 to 14 years old tolerate one-grain doses hypodermatically very well, and are benefited. He treated 120 cases, male, and female, young and old, without any untoward complications. It is interesting to remember that Lesser observed abdominal pains, vomiting, and bloody and mucoid diarrhœa after injections of yellow oxide, and never after calomel. The conclusion, therefore, is warranted that we can only get at the truth as regards the advantages and drawbacks peculiar to any and all preparations by the study of the experience of many men. It is never well to rely fully upon the assertions of the exploiter of a new mercurial preparation or combination. Thus we find that Dampekoff used the yellow oxide upon 179 syphilitic women, and that "neither intense pain nor suppuration was produced." Yet these women absolutely refused to allow the continuation of the treatment by reason of the severity of the pain. Then, on the other hand, Reshetnikoff, in the course of 1800 injections of yellow oxide, suspended in vaseline oil, made into the gluteal regions, never met with an instance of local suppuration, and only once saw a diffuse sanguinolent infiltration, which disappeared without any bad result."

(*e*). The neutral salicylate of mercury.

(*f*). Thymolate of mercury.

(*g*.) The black oxide, protiodide, red oxide, tannate, sulphate, turpeth mineral and cinnabar have all been used.

This does not begin to complete the formidable list of therapeutic suggestions that have been made, and, unfortunately for the patient, acted upon during the last few years.

The positive objections to it I have already sufficiently considered. Marked pain, sensitive nodosities, cellulitis, sloughing and abscess, liability to disfiguring and permanent cicatrices, to a sudden and grave type of stomatitis, to violent enterocolitis, to pseudo-paralyses, albuminuria, pulmonary embolism, etc., even if they occur in but a small percentage of cases, make up a sufficiently formidable list of possible accidents to warrant a reasonable hesitation before giving up older and well-tried methods, practically free from danger, in favor of this one.

The objections to it by the patients themselves are a serious obstacle, in this country at least, to the practical success of the method. Even our hospital and dispensary cases are a much more independent class than the same sort of people abroad, and cannot be subjected to wholesale experimentation with the same impunity. In Paris, Fournier has called attention to the fact that syphilitics flocked from the hospitals where this method was being tried to his service. In private practice here it would certainly be difficult of adoption, and while it might be attended by the rapid disappearance of symptoms, there would often be an equally rapid disappearance of patients.

The figures which are gradually accumulating, tend already to show that its employment, according to current formulæ, brings with it another danger, viz., that involved in the encouragement of insufficient treatment, in the dependence upon the short and heroic courses, which, as Hutchinson says, are often followed by the gravest and most serious tertiary phenomena.

The claim that by a few injections the time of treatment can be measured in months, or even in weeks, instead of years, would seem, as Mauriac has said, to involve the idea that mercury given hypodermatically acquires some new and powerful curative property which, given in

other ways, it does not possess. As a matter of fact, when we inject the insoluble salts, we are merely leaving the chemistry of their transformation into the soluble compounds to the tissues themselves; when we inject the soluble salts we are simply reaching the general circulation by a somewhat more direct method than when we approach it through the capillaries and absorbents of the skin or the gastro-intestinal tract.

I believe that, on the whole, while the final outcome of the experiences of the last few years will doubtless be for the advantage of science and the extension of our therapeutic methods, the information thus acquired will be at the expense of many patients who will suffer from the direct consequences of the method itself or succumb to the ultimate development of insufficiently treated syphilis.

In England, Hutchinson, who is, *facile princeps*, the leader of British syphilographers (and who, in my opinion, is, with the possible exception of Fournier, the leading syphilograper of the world) says: "Hypodermatic injection has come but little into employment in English practice, nor does it appear to increase in favor with those Continental surgeons who at one time thought highest of it."

In this country Taylor, so far as I know, voices the prevailing sentiment among specialists in this branch when he says: "The extent of the literature of hypodermatic injections in syphilis contributed within the past ten or twelve years is simply appalling, and there is really very little which is of practical value. It will be seen that almost every preparation of mercury has been experimented with in the hypodermatic injection treatment, and that the chemist's art has been sorely taxed to produce new preparations. Each new preparation has been exploited as the ideal of perfection, and in most cases a hearty welcome has been accorded it, so that a witty German reviewer has made the following paraphrase of an old maxim applicable to the subject: 'De novis nil nisi bonum.'"

As to the injection of insoluble preparations, he says he has no leaning toward its employment, and that he is firmly convinced that it will never be used as a systematic treatment extending over a period of years. He adds: "It is a treatment which is generally irksome and repulsive to patients, always attended with more or less discomfort and pain, and often producing destructive subcutaneous lesions over the body, which cause mental and physical suffering, and which of necessity must impair the patient's health and strength. In some cases we have seen, it has been known to imperil and to destroy life."

The soluble preparations he uses, as do most of us under various limitations.

In the light of the evidence presented above, it seems to me safe to assert that: The hypodermatic treatment of syphilis has not as yet shown results which warrant its adoption as a routine method to the exclusion of or in reference to other methods, but, on the contrary, has some apparently insuperable disadvantages and even dangers which render it improbable that it ever will be so adopted.

2. The circumstances under which hypodermatic medication should be employed may be summarized as follows: *a.* Those cases in which other methods of treatment have been tried and failed. *b.* Those cases in which, owing to idiosyncrasy or intercurrent disease, the skin and the digestive tract cannot be used for the introduction of mercury. *c.* Those cases in which, owing to grave and advancing lesions, rapid mercurialization is absolutely necessary. *d.* Those cases in which obstinate localized lesions can be most directly reached by this plan. *e.* Possibly those cases in which early differentiation between syphilis and malignant disease, or tubercular ulceration, is extremely important, should be included in this list. I certainly feel inclined to employ the method in all doubtful cases which admit of it, particularly in those conditions of the tongue which often leave the surgeon for a considerable time in doubt as to their exact nature. Anything which promises to shorten this period of doubt by rendering the therapeutic test more rapid and more certain would be of great advantage. I should, however, in such instances feel obliged to use potassium iodide by the mouth at the same time. *f.* A theoretical possibility of the employment of mercury hypodermatically has suggested itself to me, but I have not as yet actually employed it. It may be that its use by this method will aid in shortening the period of doubt which often intervenes between the appearance of the primary sore and

the development of general adenopathy or of the exanthemata. If, in the presence of a sore of uncertain character, the employment of mercury hypodermatically resulted in rapid cicatrization, no local treatment being employed other than cleanliness, it might occasionally throw light upon the case without being open to all the objections which attend the systematic and slower administration of mercury by the mouth. It is possible that the idea is worth a trial in exceptional cases, but I do not think it should be adopted as a routine practice.

3. As to the choice between the two great classes of mercurials, the soluble salts are to be preferred to the insoluble in the large majority of cases, as more exact in the matter of dosage and much less dangerous and less likely to be followed by local disturbances. They are always to be used when there is need for rapid mercurialization.

The insoluble salts should probably be reserved for those cases in which frequent visits to the surgeon are impossible and in which no contra-indications exist. In cases of defective kidneys, diabetes, profound anæmia, marked atheroma, great debility, etc., such methods are dangerous, and the case, even if urgent, will probably do better under some other form of treatment.

4. Finally, as to the special preparation to be employed: Among the soluble salts the bichloride is probably to be preferred. The results from its use are not strikingly different from those obtained from the other compounds of this class, but its stability and great solubility and its germicidal qualities seem to warrant its selection. The disadvantage is the pain which it causes, but the evidence in this direction shows that in the hands of impartial investigators, not responsible for the introduction of the particular substance employed, each of the salts on the list produces a considerable amount of pain and a not inconsiderable number of accidents or complications. Probably the bichloride is freer from objectionable features, in respect especially to the production of suppuration, than any of the salts of mercury.

Among the insoluble salts calomel and the yellow oxide are to be preferred. It would appear that the latter is a little less active, but at the same time much less irritating. Gray oil is the most available form of administering metallic mercury.

---

## A COMPOUND DISLOCATION OF THE LEFT ANKLE, AND FRACTURE OF THE INTERNAL MALLEOLUS—ASTRAGALUS AND INTERNAL MALLEOUS EXCISED.

CHARLES B. WILLIAMS,* A. B., M. D., Philadelphia.

F. M., aet. 43; white; married; was admitted to the Pennsylvania Hospital on the afternoon of June 29, 1892, suffering with a compound dislocation of his left internal malleolus, the result of a fall from the third story of a building which he was painting. There was a large lacerated wound over the external malleolus (or the place where it is normaly situated,—for in this man the external malleolus, as well as the fourth toe with its accompanying metatarsal bone were congenitally absent) through which wound protruded a portion of the articulating surface of the astragalus. The foot was warm and the arteries intact. The patient was considerably shocked upon admission, temperature 99°, pulse soft and compressible. He was given hypodermics of strychninæ sulph. gr. 1-40 with tr. digitalis m. x. before the operation, as well as several hypodermics of ether and one of atropiæ sulph. gr. 1-120 during the operation.

*Operation.* The patient was etherized, the wound slightly enlarged, and the astragalus severed from its attachments by means of a probe pointed knife, and then excised. In like manner, the internal malleolus was also removed. The articulating surface of the tibia was next sawed of. As the anterior and posterior tibial arteries were uninjured, only a few small

*Ex-resident physician Penna. Hospital; Assistant surgeon to Methodist Episcopal Hospital.

veins required ligation. After a rubber drainage tube had been inserted in the wound, its edges were united by means of silver wire sutures. The limb was dressed antiseptically and placed in a fracture box.

The patient was now ordered ammon. carb. gr. v. every ½ hour, whiskey drs. ij. hourly, and tr. digitalis gtt. v. every four hours, the frequency of the doses to be diminished as soon as the patient reacted.

At 9 P. M. there was considerable oozing through the dressings which necessitated their being reinforced with bichloride cotton.

June 30, 1892. Oozing from the wound has ceased. Limb is in good position. Patient complains of his back hurting him, for which warm leadwater and laudanum was ordered. Has no pain in his ankle.

July 3, 1892. Limb dressed to-day. The edges of the wound appear to be well approximated. No discharge through the drainage tube, which was now shortened a little.

July 13, 1892. Dressed yesterday. All of the silver sutures were removed. There was but little discharge. The tube was further shortened and the limb dressed as before. The position of the foot and ankle is excellent.

August 13, 1892. The fracture-box dressing was discontinued to-day. There is scarcely any discharge from the wound now. There seems to be some slight motion in the ankle-joint. In place of the fracture-box two lateral splints of Russian felt, moulded accurately to fit the limb, were applied with a small antiseptic dressing, and the patient allowed to be up and about in a wheeled chair.

August 16, 1892. Wound is entirely healed. The patient walks quite well with the aid of crutches.

August 17, 1892. The patient went out on a pass to-day and eloped.

September 7, 1892. The patient came back to the hospital to-day. He still uses crutches. There is some slight motion in the ankle-joint. The wound has entirely healed. The shortening amounts to about 2½ inches and the patient walks on the ball of his foot with the heel elevated. Ordered to procure a shoe with a "built-up" sole.

The patient walked into the hospital about four months ago. He had abandoned crutches and was wearing a shoe with only the heel "built up." Consequently he experienced considerable discomfort in walking and his ankle tired very easily. There was considerable motian to be observed in the ankle now. The patient was ordered to have the sole of the shoe, as well as the heel, built up for 2½ inches and then to return and report to the hospital. This last request he has never obeyed.

---

### Aristol in Hemorrhoids.

To establish a radical cure, all causes to be ascribed to a faulty diet strong drinks or want of exercise must first be removed, says Dr. Engle (*Med. Summ*). Then every morning and night, and in severe cases every three or four hours, about one ounce of cold water is injected into the rectum and allowed to remain as long as possible. Morning and night the following suppository is applied:

℞ Extracti opii..... grs. iij
Extracti belladonnae..... gr. j
Quiniae muriat.,..... grs. xxvj
Aristol..... 3j
Olei theobrom.,
Cerae albae.....āā q. s.

M. Et fiant suppositoria No. vi.
Sig.—One, morning and night.

Immediately after each movement of the bowels the following salve spread over the point of the index finger is pushed up into the rectum for about one and a half inches, and some upward pressure is exerted by the external sphincter.

℞ Unguent zinci benzoat..... 3j
Balsam Peruvian..... 3j
Aristol..... grs. xxx

M. Ft. Ungt.
Sig.—Externally.

While, internally from one to two heaped teaspoonfuls, in plenty of water, are taken two or three times daily of the following powder:

℞ Sulphur. flor.,
Potass. bitartrat.,.....āā 3j

Mt. Ft. pulvis.

—*Medical Review.*

---

For Pain in the Ear from inflammation, Dr. John Dunn (quoted in *La Semaine Medicale*) recommends the following:

℞ Menthol pulv.,
Camphor. pulv.,.....āā gr. xx
Vaseline liquid..... f3j

M.
Sig.—Instill a few drops into the ears several times a day.

---

### For Vomiting after Etherization.

Prof. Hare (*Coll. and Clin. Record*) recommends the following:

℞ Tincturæ opii deodoratæ..... gtts. xxx
Sodii bromidi ..... grs. xxx
Aquæ amyli..... 3ij or iij

M. Sig.—As an enema.

# SOCIETY REPORTS.

## THE MEDICO-CHIRURGICAL SOCIETY, OF LOUISVILLE.

*Stated Meeting April 14, 1893.*

THE PRESIDENT, Dr. F. C. Simpson, in the Chair.

### STENOSIS OF THE ŒSOPHAGUS.

DR. F. C. WILSON: This specimen is from a patient, male, aged about fifty-seven years, who had always been perfectly healthy, that is he had never been under a physician's charge, although never robust in appearance. He commenced having some difficulty in swallowing which gradually increased to such extent that he became uneasy about it, and he began at the same time to vomit. He never had any very severe pain of any sort; gave no history of having swallowed any poison or corrosive substance, and was of course at a loss to account for the trouble. When I saw him, I found that he was able to swallow liquids, but in an irregular way. Sometimes he would be able to swallow then for a day or two, at other times for some days he would hardly be able to get anything down. When anything would pass down, after a while a good deal of it would be regurgitated. He gradually grew worse until he was considerably emaciated. I questioned him concerning his symptoms, as to the possible inheritance of cancerous trouble, as to his having swallowed any substance like a piece of bone, or any corrosive material, but found that he gave no history of anything of that nature. I could locate by auscultation some obstruction during the act of swallowing near the lower end of the œsophagus; I could hear it distinctly as he would swallow while I listened over the course of the œsophagus. I suggested to him that I explore the œsophagus, at the same time pass any obstruction that might be there by means of the bougie or feeding tube. During auscultation I listened carefully for evidence of aneurism or bruit thinking there might possibly be some obstruction due to that, but nothing of the sort could be heard. The patient complained of no pain such as we usually find in aneurism occurring in proximity to the vertebral column; we know that gives rise to severe boring pain due to breaking down of these vertebræ by impact of the developing tumor. Nothing of the kind could be elicited in the history and there was no evidence of any aneurismal enlargement.

I made an engagement with him and visited him for the purpose of introducing a tube. He was a very timid and nervous man and I had some difficulty in passing the tube, but I could distinctly recognize the obstruction when that point was reached. I succeeded in passing an ordinary rubber feeding tube and poured through it a fairly good meal of milk and after that for several days he was able to swallow with a great deal more ease. I made another engagement with him for several days later, but before the time was reached he sent word that he was swallowing so much better he believed he would postpone it. I saw no more of him, and six months afterwards I saw notice of his death. He passed into the hands of some Homœopathic physician; he grew gradually worse and more emaciated, and finally death occured from exhaustion. I was called to make a post mortem in the case. I made the autopsy and secured this specimen which I present here to-night with the idea of getting the opinion of the society as to the nature of the enlargement. No microscopical examination has been made thus far. In making the post morten examination I opened the chest and found no trouble to account for death until I reached the œsophagus. I removed the entire mass, œsophagus and stomach, and in slitting open the œsophagus I found near the lower extremity some excrescence-like growths which involved the lower portion of the œsophagus and extended through the cardiac orifice into the stomach. This enlargement or growth looked very much like an excrescence, not nodulated and not hard. The stomach was very much contracted. There was no involvement of the neighboring organs, of the liver or spleen. I believe Dr. Coomes saw the case a number of times and passed the bougie, but what his opinion was as to the nature of the trouble, I am unable to say. One Homœopathic physician

who saw the patient, I think, made diagonsis of aneurismal enlargement of the aorta. Nothing except a careful microscopical examination can clear up the exact nature of the case

DISCUSSION.

Dr. J. A. Larrabee: I have had quite a number of cases of stricture of the œsophagus, eight or ten probably, covering my experience in practice. I have one now that I would like to turn over to the Homœopaths. I think this is a capital idea. The patient referred to came to my office about two weeks ago; I started in by passing an Oliver bougie, smallest size. After three dilatations in that way I passed the larger one, which is the largest size of four bougies in the set manufactured by Oliver. I told him I thought that amount of dilatation would give him some relief and fully expected it to do so, whether it was temporary or otherwise, but contrary to my expectations, he reported that it was no better an hour afterward so far as swallowing was concerned than it was an hour before. I scraped some of the material from the tube after withdrawal and handed it to Dr. Vissman for examination. This patient is not emaciated and presents a very fair appearance. There is no cancerous cachexia, neither has he a cancerous history. Now I believe this man is going the way of the other case of stricture of the œsaphagus reported, but just what the nature of the stricture is, I do not know. The case has only been under my observation for two weeks, and he has been unable to swallow anything except fluids. Auscultation locates the obstruction about midway of the œsophagus, you can hear it "chuck" there just as plainly as you could a bucket, then the fluid slowly trickles down.

Dr. A. M. Cartledge: It seems to me in cases of this character the first thing to establish is "stricture of the œsophagus" after that fact has once been established usually there is but little difficulty in determining the nature. Certainly there should be very little trouble after death has taken place. It seems to me differentiation should be very easy. True stenosis of the œsophagus is cicatrical or malignant. Cicatrical stenosis is the result of syphilitic ulceration, more rarely tuberculous and very commonly the result of trauma.

In the case reported by Dr. Wilson, without a microscopical examination I do not think anyone should pass a judgment, but my opinion is that it is clearly malignant disease. It is not sypilitic, it is not tuberculous, and I take it from the size of the deposit and the macroscopical appearance that it is carcinoma, and believe that the microscope will prove it.

Dr. J. A. Larrabee: Would it be possible if it were carcinoma without any ulcerative stage set up, to have told from the secretions whether it was cancer or not?

Dr. Wm. Vissman (Visiting): I do not think there is any possible way of telling whether it is cancerous or tuberculous, or anything else, unless you get a particle of the tumor, and you could not get this without there was a breaking down.

Concerning the specimen exhibited by Dr. Wilson: From a macroscopical examination I think there is no doubt about its being a carcinoma. One peculiarity about the tumor is that we cannot discover the exact line of the stomach, that is where the stomach has been taken off. Another peculiarity is that carcinoma of the œsophagus very seldom or never, we might say, extends into the stomach. It may be that the microscope will show that this is nothing more nor less than a carcinoma of the œsophagus.

Dr. F. C. Wilson: I had mapped out a plan of management of the case which possibly may have had something to do with scaring him off. I had spoken either to the patient himself or a friend of the advisability of feeding him in the way that I had attempted to do, and if that failed then of putting a tube into the stomach from the outside so that he might be fed in that way. Of course, if the tumor proves to be malignant in character, it would eventually have caused death, but I believe his life might have been prolonged by the insertion of a tube into the stomach. He was greatly emaciated, and certainly died from sheer exhaustion. Had the tube been inserted in the stomach from the outside, his life might have been prolonged possibly several months at least.

Note: A subsequent microscopical examination of the specimen by Dr. Vissman clearly proves the trouble to have been of a cancerous nature.

Cornelius Skinner, M.D., then read a paper on

CONSTIPATION.

Of all minor troubles to which the attention of the practitioner is called, I am persuaded that constipation is the most common and, I am equally bold to say, the most intractable in its cure. It is my purpose in this short paper not to treat of constipation in all of its forms, but to take up that one in which constipation seems to be the disease and not the symptom. Stricture, fissure, hemorrhoids, spinal lesions, tumors, etc., will not be spoken of, but rather that form in which we find tardy and difficult defecation, with hard, scibalous stools. We will not use the time in rehashing the symptoms and effects in general, but go direct to the form in question.

A large majority of these patients we find among the women, and most usually from 15 to 30 years of age. The usual chain of symptoms are given and, on casual questioning, we find that they have had time for and paid more attention to everything else in life than to the bowels. They are punctilious in all engagements, regular at meals, etc., but not at stools. The most trivial affairs, social and otherwise, causing a postponement of one of the most important calls of nature to a more convenient season, which is usually the next day. Again, we find not all typewriters, teachers, etc., or people who lead a sedentary life, but just as often floor-walkers, postmen, or those who take a good deal of exercise, with good digestions and appetites sufficient. One thing is noticed in, I might say, all of this class, and I consider it the prime cause of all trouble, viz: These people do not drink a sufficient quantity in twenty-four hours for nature's demands. They are noticeably small drinkers, and never take water unless prompted by thirst or at meals, and then will drink to excess. The majority of people in general drink too much while eating, thus diluting the juices of digestion to a degree which will eventually impair digestion. It is not easy for us to realize the amount of water thrown off by a healthy man or woman in twenty-four hours:

By the kidneys we lose.....42 ounces.
By the lungs we lose .....23 ounces.
By the skin we lose.....15 ounces.

Now contrast this with the amount taken in during the same time, and we find little enough left for the bowels under most favorable conditions, and when we lessen this by one-fourth or one-half, we find nothing left to keep the stools soft and in the proper condition to be, by peristalsis, packed down into the sigmoid, ready for prompt and easy expulsion.

Constipation may be called the machine of "perpetual motion;" for, when once started, it perpetuates itself until checked by proper causes. Now I admit that we must find the cause for all things, and then remove that cause in order to effect a cure; and, in this very common form just spoken of, to relieve it, we have simply to furnish that deficiency of water in the proper way, and the cure is effected.

It is my custom not to employ any of the waters now sold for constipation; first, because they will not cure, but establish in the bowel that habit which we want to avoid, of waiting to be driven into action by laxatives; secondly, they are expensive.

As I have said before, this water should not be taken at meals, nor too close to the meal hour, but long enough before in order that it may have time by absorption and otherwise to pass out of the stomach into the circulation and bowels below. I have the patients to drink an ordinary tumbler full of cold water thirty minutes before breakfast, dinner and supper, and to take the fourth at retiring, giving sixteen ounces or one pint in addition to that taken at meals as coffee, milk or tea, and during the day when thirsty. Except in very obstinate cases this simple remedy gives me most gratifying results. In those intractable cases I generally use a little pill of aloes, belladonna, strychnia and podophyllin each night or less frequently during the week as the exigencies of the case require. There will be failures on the part of the water and much disappointment to a few patients who put their trust in this remedy, but if this plan is followed systematically in from two to six weeks we will get good results. As an apparent exception I wish to mention a case of constipation that has given me no little concern in the past three weeks.

Patient a tall, slender woman, raised in the country, of good health and family history; age thirty-nine years; married about two years; baby five months old. This woman first consulted me in the beginning of gestation for nausea and a small tumor in the left groin just about the site of inguinal hernia. No positive

diagnosis of tumor was made, but I assured her that it would play no part in her confinement, and advised leaving it alone, there being no pain or other symptoms to attract attention. Constipation was quite a factor during gestation, and remained so afterwards, but was tolerably well controlled by the water treatment with the addition of a small glass of Hunyadi water before breakfast. On the night of March 21st I was called and found her suffering intense pain just over the symphysis and tumor mentioned; pain did not intermit but was continuous; tumor very sensitive to touch, almost constant nausea. My first impression was strangulated hernia; bowels had moved in the morning after the water was taken; pain began at five P. M. and this was eleven P. M. Usual domestic remedies had no effect; pulse 95°; temperature 98½° F. After watching the pain for an hour and still hesitating between strangulated hernia and colic, and realizing the importance of a positive dicision, I called Dr. Rodman in consultation. The Doctor meeting me in one hour, pain in the meantime had shifted into the epigastric region and had become much less. This changed the aspect somewhat, and we both concurred in its not being strangulation but colic. We concluded our visit at three A. M., but left a hypodermatic of morphia and atropia to be given by the husband if the pain grew worse. I saw the patient next morning at nine o'clock. She was comfortable, but much nauseated; pulse 75, temperature 98½° F. Nausea lasted all day and following night. On the morning of the 23d still great nausea; pulse 100, temperature normal; hot water ordered, which controlled nausea. Met Dr. Rodman on the street, and we agreed to give calomel in one-grain doses until bowels were moved or six grains had been taken. At 2 P. M., pulse 110, temperature normal; patient very restless and slightly flighty; calomel was begun. Dr. Rodman saw her with me at 10.30 P. M. Pulse 120, temperature normal; restlessness increased, with very marked flightiness; no move from bowels. We now believed that there was some internal obstruction, and so expressed ourselves to the husband and, at the same time decided to open the abdomen in the early morning if there was no change for the better. This he very positively sat upon, because her mother, living in the country, was not here to counsel. However, we felt that all responsibility had been assumed by the husband.

Expecting to find the patient worse by morning, we left; but with the determination of going back early and prepared to operate at once. Drs. Mathews, Cecil and Bullock were asked to meet us; we met at eight A.M. 24th, to find pulse 100, a drop of 20, temperature 98½° F., no restlessness, and patient much better. Since the mother could not reach the city before seven P. M., we all decided to wait. Patient held her own until the 30th, when nausea again appeared with pulse 120 and temperature 99½° F. Calomel was given in doses of one grain every hour for six hours but with no effect. On the afternoon of the first instant, castor oil in capsules one drachm each, was given every two hours to be kept up until bowels moved, or eight were given; after twelve hours bowels moved copiously and thus ended to us a most puzzling case.

I will say that frequent colon irrigations were made by myself, with and without glycerine.

The point I want to make in the paper is, in this class of cases where we find no especial reason for the constipation, water given in the manner as described will result in a cure in most of them. The results of this treatment in my practice have been most gratifying.

DISCUSSION.

Dr. J. A. Larrabee: I do not think a paper as interesting and instructive as the one presented by Dr. Skinner ought to go without remarks. I will say that when I received notification of this meeting and saw the name "Constipation" as the subject of the essay, I felt "bound" to come. The importance of what Dr. Skinner has said in regard to a "minor" condition becomes in the mind of every practitioner a "major" condition. The importance attached to the movements of the bowels may be best estimated by the love of people for cathartics. All a man has to do to make his fortune is to get up a cathartic pill or a powder for the same purpose. The desire of the community to be purged amounts almost to insanity. I do not suppose there is a board fence this side of Bullitt County that has not painted upon it something for regulating the bowels. There is not a peak in the Rocky Mount-

ains so high that somebody has not climbed up to put Vinegar Bitters or Carter's Liver Pills on it, so you can judge somewhat of the importance attached to purgative medicines. Regulating the system and keeping the bowels in a soluble condition cannot be over-estimated, and I am one of those who believe in the poisonous effects of retained material in the bowels; if we have a disease called "Uremia" from retention of the urine, I do not see why we cannot have diseases dependent upon "stercoræmia." Many people may have died from causes produced entirely by constipation.

There is one point which has struck me all along while engaged in the practice of medicine, and that is the success of Quacks who use nothing else than aloin purificata in the treatment of chronic diseases. You can take it for granted that when a man starts out with patent medicines, medicines which he himself has patented and advertises for the cure of chronic diseases, that he is giving aloetic purgatives, and another fact that is not sufficiently weighed by physicians in debarring the Quack is that he succeeds in relieving many of these chronic cases. Any old chronic case of anything, I do not care what it is, whether rheumatism, gout or whatever it may be, is more or less relieved by a severe purging. That is where the Quacks get in their work, they help every case of that nature, old patients, men who have been drinking a good deal. I know of half a dozen cases here where old chronic cases of mine have brought medicines from men who were selling them along the street, the vilest compound ever put up, a decoction of aloes and horse aloes at that, and every one of them were relieved, and relieved for quite a while. I speak of this, gentlemen, just to call attention again to these forgotten facts of our law, where we fail in the course of treatment to secure free daily alvine dejections. We can administer a tonic, we can administer iron, tonics for anæmia, spanæmia or hydræmia and the iron does very little good; we do not get the reddened blood corpuscles, nor do we get the characteristic effects of the iron. In this particular the iron waters do more good than our iron simply because they combine purgative salts with the iron. It was the custom of the old school to purge, to vomit, and to bleed; this was the circle of therapeutics around which they moved, and certainly they were on the right track so far as purgation, dieting, etc. were concerned. I think we are forgetting a great deal of the dietary system, and our patients would probably be better off if the old regime were adhered to a little more closely. For instance, I see every day cathartics ordered, of different kinds, chologogues, etc., and the patient allowed to eat what he pleases; the old style was to make corn meal gruel, or oat meal gruel and while the patient was being purged he had to take this kind of a diet. Nothing has been said about the idea that constipation is dependent upon the rapid absorption of water from the intestinal tract. The rectum is a drying machine if it is anything, and so situated as to prevent our becoming nuisances to ourselves, taking up the water from the rectum and drying the feces in the proper shape. Now those people who are constipated have very rapid absorption of water, unless you force large quantities upon them, which means certain cure; it need not be water laden with medicinal elements, simply water (being sure that it is fresh) and use it "on account of its being water," preventing this rapid absorption and allow the feces to be liquid.

The case reported by Dr. Skinner is an exceedingly instructive one, and one which comes up every now and then in practice. The Doctor has said very properly that it is a most puzzling case to present. For some reason we always think the worst about our patients; we are apt to think of appendicitis, then of colic, then of intussusception, etc.; and in this case there seems to have been about this line of symptoms. Yet it was evidently a case of torpidity of the bowels, with no great accumulation of fecal matter.

Referring to Dr. Skinner's statement that many of these cases take sufficient exercise. This is not in accord with my observations of chronic constipation. I believe that the cæcum is so constructed, whether it is the design of nature to do this or not, that walking exercise has an effect like rubbing the cæcum, on account of the muscles which pass behind it. The cæcum is moved when a person is walking, which is not the case by any other means, except possibly riding a bicycle; and this point I understand is to be brought out

later in this society, as a committee has been appointed to make some investigations in that direction.

Now as to medicinal agents. We all know that purgatives, given *per se*, are injurious in a case of this kind. They call upon the peristaltic action of the bowels; and every time this is called upon the natural power of peristalsis in the bowel is lessened. Consequently, the more purgatives a person takes the more he must take, and all of them after a while lose their effect. In those cases where medication becomes necessary, I believe it is far more sensible to administer an agent which shall paralyze the inhibitory nervous supply and stimulate the sympathetic nervous supply. For this purpose I do not think there is anything equal to belladonna and strychnine. The "little pill" of belladonna, aloine and strychnine I believe to be the best known combination. These are agents which do the work of paralyzing, and I believe, in these cases, if morphine and atropine were given hypodermatically, you would have the desired effect without calomel. The check on the pneumogastric nerve as it is distributed to the bowel is lessened by belladonna; it paralyzes that nerve, allowing the feces to become free. I do not think we have, in the list of medicines, an agent which will do the work that belladonna does in this particular; not belladonna alone, but all its congeneric mydriatics, and all the mydriatics, act in the same way if we add to them strychnine, which possesses in itself a tonicity for the bowels.

I have seen several cass of chronic constipation in infants. In these cases I have found that rubbing or kneeding the bowels with the hands for five or ten minutes produces an alvine dejection. We want of course to increase the tone of the bowels but I would urge the use of simply large quantities of water as this alone will usually produce catharsis.

Dr. D. T. Smith: The subject up for dicussion as stated by the previous speaker is regarded as one of special importance. Dr. Skinner has narrowed the discussion very much by limiting it to functional constipation. The case reported by him may or may not have an application as illustrating a principle; I rather think it has not. It may be more reasonable to suppose that there is an adhesion at some point in the colon in the case of his patient and the peristalsis arising at that point after narrowing might be sufficient to cause that condition. We very frequently find that. However we do not often observe vomiting in cases of funtional obstruction. There is sometimes paralysis or peritonitis of that small portion of the intestine, which might be sufficient to cause death. I think from the history that the trouble is simply an adhesion causing a narrowing of the intestine or an arrest of peristalsis at same point.

Concerning the treatment of constipation: As this is a condition which is usually suspected to arise from an accumulation or obstruction of material that ought to have passed out with the fecal discharges, the most important thing is to relieve the patient of this obstruction and then administer remedies which are known to have a stimulating effect upon the bowels.

I reported before this society sometime ago, a case which Dr. Roberts saw with me, in which preparations were not exactly made, nevertheless everything was gotten in readiness to do an exploratory laparotomy for the relief of constipation. There was stercoraceous vomiting and other symptoms of obstruction. However, before the time to operate, we gave the patient a pint of sweet oil, knowing it to to be a safe remedy in any attack, and the result was an almost immediate disappearance of the distressing symptoms, the patient recovered and is in fine health to-day. In this case there was retroversion of the uterus, some post-pelvic peritonitis and evidence of adhesions which probably accounted for the trouble.

As Dr. Larrabee has said, the two remedies most relied upon in the treatment of constipation, as they do not irritate, are belladonna and strychnine, because they stimulate the muscular coat of the bowel, and by stimulating its action developing a strength that overcomes the atonic condition. As far back as 1861, I know that belladonna, nux vomica and compound extract of colocynth were given in this way. Aloes act as a stimulant in a similar way.

In regard to the use of water: There are two respects in which water will be beneficial. In the morning when we rise (with those of us who are subject to an accumulation of mucus in the lungs and

stomach) the whole alimentary canal is covered with mucus accumulated during the night, and water taken early and freely will reach the lower bowel without being absorbed. Ordinarily there is an abundance of water passing into the blood and then back into the large bowel because we know a considerable number of substances are carried into the circulation and then back again through the large intestine, not reaching the small intestine. Therefore, about the only way to have water reach the small intestine unabsorbed is by taking it in the early morning. I find many patients unable to take more than a glassful immediately on rising owing to the nausea produced, and it becomes necessary for them to wait for a few minutes until this feeling passes off before taking a second glass. I direct them to take three or four glasses, if they find it necessary, or if less fails to do the work, until a sufficient quantity of water is taken before breakfast to secure an action on the bowels shortly afterward. I think one of the most important things in this connection is that we should have a certain time for evacuation each day. The absence of a fixed period for an effort at stool may be the cause of the trouble in many of these cases. Any person not giving the bowels opportunity to act at a given time will necessarily become constipated, even if the alimentary canal is in a healthy condition; then I think it is not a bad plan for awhile to induce excessive or over-action.

I believe if proper attention were given to the matter of having a regular period for evacuation of the bowels, and patients instructed to drink water in the early morning, and a sufficient amount later in the day, that the administration of cathartics could be done away with to a great extent. I am aware while I am saying this that there are a great many people who cannot drink water, cases of of gouty diathesis, etc., and for this class of people salines can be given which will carry the water through the stomach, which otherwise could not be done.

Dr. F. C. Wilson: I have been in the habit of using hot as well as cold water. Hot water is not quite as pleasant perhaps, but with the addition of a little lemon juice or salt it becomes really palatable and patients get very fond of it. I believe hot water preferable to cold, as it reduces the supply of blood in the capillaries of the walls of the stomach, which thus warmed up is driven directly through the liver, through the pancreas and neighboring organs, stimulating them to increased activity, and we have necessarily increased supply of bile. On the other hand it increases the digestive fluid supply, not only in the stomach itself but in the pancreas, so that digestion is improved and at the same time peristaltic action is stimulated.

Dr. J. G. Cecil: I have listened with a great deal of interest to the excellent paper read by Dr. Skinner, and to those who have already spoken. I fully agree that the subject of constipation cannot be too freely discussed, as it is a matter of very considerable importance. If I am a "routinist" in anything it is in giving purgatives, and I very seldom undertake the treatment of a case of any kind without very carefully inquiring into the condition of the bowels and generally find that a purgative is demanded, and usually also find that all medicines as Dr. Larrabee has very properly said, are increased in their efficiency, by having the alimentary canal cleared out before their administration, I have for a long time been very much of the same opinion as the essayist with regard to the administration of water and have often recommended it. I believe that the beneficial effects derived from many of the mineral springs which are visited owing to their advertised efficiency for constipation, depend largely perhaps, upon the water taken because it is water and not so much from the fact that it contains medicinal properties; quite so much also upon the quantity and regularity with which it is taken.

Concerning the point raised by Dr. Larrabee in regard to constipation in infants: This is a matter that has caused me a great deal of trouble in my practice. Very frequently infants nursing or feeding upon the bottle, become obstinately constipated and I have recently been in the habit of advising that the children be given water. I think this is a point that is often overlooked in the treatment of children, the mother or nurse naturally assuming that the infant gets sufficient quantity of water in the milk. I believe constipation in many of them is very agreeably affected and frequently cured by the administration of water.

The case reported by Dr. Skinner is one of extreme interest; the history shows that this woman was nearing a point where surgical interference was urgently demanded. However, at the first visit I made (having seen the patient after she had been constipated several days, and after large quantities of purgative medicines had been given, after she had had injections also and with the history of the case given before I saw her), I was led to suspect a very different condition from what I really found; the patient was in a fairly good condition, not particularly anxious in expression, not restless, not tympanitic, no fever, no tenderness, fairly good pulse, and thoroughly rational; and under the most careful and searching examination, I was unable to locate any tender spot or tumor in the abdominal cavity or any accumulation of fecal matter. The hernia or whatever it was in the inguinal region to my mind had no bearing upon the case. I think if there had been an adhesion or stricture of the bowel at any point, as hinted at by Dr. Smith, we would have had a different line of symptoms from those present. I would hardly have expected to have seen an amelioration of symptoms without perfect relief, and I would have certainly expected to find an accumulation of fecal matter above this constriction, which we could not locate. I do not think I remember to have ever seen a case that resisted such heroic doses of purgative medicines as this woman did. Probably a week after my first visit Dr. Skinner met me on the street and told me that she was still constipated; he had tried injections and flushing the bowels (Dr. Mathews' suggestion), which I am sure was followed out with a thoroughness not often practiced, as Dr. Skinner did the work himself, and had there been simply an ordinary constipation of the lower bowel, I am satisfied this treatment would have solved the problem. But as already indicated, there was no effect. She was benefitted by the amount of water used in these injections, as I understand several were retained. To my mind there is no cause assignable for the obstinate constipation in this case, other than torpidity of the liver and bowels. Possibly there might have been temporary paresis of the small bowel; the constipation I am satisfied was in the small bowel.

Dr. T. S. Bullock: I only want to speak of the manner in which the flushing was done in this case: It was done through a rectal tube passed to the sigmoid flexure, a copious amount of fluid being used as already indicated, and if there had been an accumulation of fecal matter in the larger bowel, and I am inclined to think that it would have been very promptly removed by these repeated large amounts of water. Only a very small quantity of hard fecal matter was brought away by the injections.

Dr. W. Carroll Chapman (visiting): I would like to mention one point in this connection, which seems to me to come under the head of functional causes of constipation, especially in women, and that is lack of effort, which is often due, I find, to pain due to congestion and the attending sensitiveness in the genital organs—the ovaries, uterus or vagina. I have often seen women who were not constipated so far as desire goes, but complained that when they wanted to have stools they could not do so, excepting the effort caused them so much pain that they would not make sufficient effort to produce an evacuation. It seems to me where this is the case, and I am satisfied that in women it does occur frequently, we should by hot injections or special applications, as may seem best, endeavor to relieve this condition which would doubtless relieve or possibly entirely cure the constipation.

Dr. J. A. Larrabee: The element of colic has been alluded to, which was entirely overlooked by me in my former remarks concerning Dr. Skinner's case. How are we to determine that it was colic? One feature of one kind of constipation that ought to be alluded to is that caused not by paralysis but by constriction. For example take a case of lead colic, if you please, a case in which you have a portion of the intestines ligated by a circle of fibrous material with extreme pain. What kind of a purgative would you give there? Certainly any effort to increase the peristaltic action would increase the trouble. Under these circumstances I believe that large doses of opium will produce an action from the bowels, an agent which it is well known will produce constipation. But under these conditions an action is produced upon purely scientific principles, it paralyzes the circular fibres. Whenever I see a case of lead colic and obtain that

history, (I usually find that the patient has already taken large quantities of purgative medicines without effect) I administer large doses of opium and it has been my experience that relief follows. Instead of paresis we can have an oposite condition of constriction by the circular fibres.

Dr. D. T. Smith: I intended in my former remarks to refer to Dr. Larrabee's statement as to the way in which belladonna affects the bowel. I believe that the doctor claimed that the good effects of this drug were produced by removing inhibition. I have never heard of any teaching that belladonna acts in this way. There are no ganglia situated in the walls of the intestines stimulating their action, as there are in the heart. Belladonna we know, acts doubly upon the heart; acts directly upon the heart muscles, at least, acts by inhibition of the motor centers from its own ganglia.

I believe that the increased peristalsis is due to direct paralysis, not to an inhibitory one, as the doctor claims.

Dr. J. A. Larrabee: All experiments upon the subject of belladonna which have been conducted by vivisection and otherwise, have shown that this above all other drugs places the intestines in peristaltic action. Wherever there is a branch of the inhibitory nerve, belladonna acts, no matter whether by the capillaries, heart, liver or otherwise; wherever inhibition goes, there stimulation goes, and both go to every part of the economy. Every action of the body is controlled by two forces, like driving a horse with two reins; between the two you get a rhythmical action, but when one or the other is crossed, a different result is obtained. Of course the effect of belladonna is through its action on the pneumogastric nerve. The benefit is derived by taking off the power of checking.

Dr. C. Skinner: Concerning the administration of morphine in the case referred to in the paper: We all thought, after it had been given, that we ought not to have left the hypodermic injection there. If I had left the atropia without the morphine, I think it would have been better, as the morphia was undoubtedly the cause of the marked symptoms the second day. I believe it is a great mistake to give a hypodermatic of morphine when you want to make a differential diagnosis in such cases.

As to constipation in infants: Water can be administered in these cases with good results just as with adults. Mothers and nurses all tell you that the baby will not take water. That may be true, but the reason is that they have never been taught to take it. After a little perseverance on the part of nurses the baby will of course take a sufficient amount of water to obtain the desired result.

As to massage: That was not mentioned in the paper, I referred simply to the water treatment.

I agree with Dr. Smith that having a stated time for evacuation of the bowels is an important factor. There is one thing above all others that a physician will observe in the treatment of constipation, and that is the little attention that these people give to periodical movements of the bowels. One reason why it is so common in women is that on account of their false modesty, or, for various reasons, they do not attend to this call of nature as they should. In this way constipation is started and then keeps itself up.

Referring to Dr. Wilson's remarks in regard to his preference for hot water: I use cold water because I think patients will take more of it, and it is easier to take. In this special class of cases where we have young women from fifteen to thirty years of age to deal with, they will not take hot water. In older people probably hot water is more preferable.

Dr. Chapman mentioned one very important thing in reference to constipation in women, that is, pain produced by any effort at stool; for instance a displaced ovary may render defecation very painful, especially if the feces have become hard, the pressure upon the prolapsed ovary will produce such pain that the patient is unable to make the necessary effort at stool. The majority of these cases are usually controlled by divulsion; you can take a case of this character and dilate the sphincter, after a short time relief will usually follow.

Dr. Bullock spoke of the injections in the case reported by me. I know that these injections were very carefully given, and were really irrigations. I used a No. 7 tube its full length. In the first or second injection probably an ounce of fecal matter came away, after this nothing was returned except the injected water; for that reason we believe that the trouble was not in the large intestine, but a torpid small bowel.

# THE MEDICAL AND SURGICAL REPORTER

ISSUED EVERY SATURDAY

ADDRESS
Care P. O. Box 843, Philadelphia.

HAROLD H. KYNETT, A. M., M. D.,
Editor.

RODERIC C. PENFIELD,
Publisher.

316-18-20 North Broad Street,
PHILADELPHIA.

TERMS:—Five Dollars a year, strictly in advance, unless otherwise specifically agreed upon. Sent three months on trial for $1.00.

REMITTANCES should be made payable only to the Publisher, and when in sums of Five Dollars or less, should be made by Postal Note, Money Order or Registered Letter.

NOTICE TO CONTRIBUTORS:—We are always glad to receive articles of value to the profession, and when used they will be paid for, or reprints supplied, as the author may elect. Where reprints are desired, writers are requested to make a note of that fact on the first page of the MS. It is well for contributors to enclose stamps for postage, that the articles may be returned if not found available.

SATURDAY, JULY 22ND, 1893.

## EDITORIAL.

### THE PREVENTION OF SURGICAL INFECTION.

Most members of the profession can remember when the relation of bacteria to wound infection was a mere hypothesis conceivable from *a priori* considerations but supported by comparatively few crudely made and half studied observations and vulnerable at every point to the keen, critical scrutiny to which every proposition is subjected. When in the unremitting search after truth, scientists put it to the test of practical utility this hypothesis deepened into conviction. Clinicians began to teach the theory of sepsis and the technique of antisepsis, at first tentatively but with increasing confidence until at length with the full assurance that the microscopic objects which they could demonstrate, cultivate, transplant by inoculation and again collect, were the tangible causes of suppuration and septic complications.

In 1886-7 Donald McLean, then of the University of Michigan, was almost the only operator who dared perform coeliotomies in the public clinic. Two years later, Dr. Goodell tried the same experiment in the Hospital of the University of Pennsylvania and considered himself justified by the results. The standard antiseptic dressing in most Philadelphia clinics at that time consisted of layer after layer of wet bichloride gauze, while the light, dry dressing was condemned on the ground that it did not adhere to the skin tightly enough to prevent the insinuation of germs beneath it. The fact was entirely overlooked that the most favorable results were achieved with the dry dressings and that the heavy, wet bichloride pack, like a poultice, softened the underlying tissues and provided one of the three requisites for septic fermentation—moisture.

It is unnecessary to allude to the inevitable "modification" by the ubiquitous parasite of genius who bores for notoriety, or to the succession of chemicals that have been in vogue for longer or shorter periods. Antisepsis, in lessening the death rate, in eliminating septic complications, in extending the field

of operative surgery and, above all, in impressively teaching the truth of its fundamental principle, asepsis, has achieved a notable triumph over all older methods.

It is perhaps remarkable that in general surgery there is no great difference in the success of those surgeons who rely upon boiling water, baked cotton, soap and the scrubbing brush—in a word cleanliness, and the success of those who have faithfully used bichloride of mercury, potassium permanganate, carbolic acid, hydronaphthol, or creolin, zinc or iodoform. Even the careless ones who occasionally let their sutures drag across the table, or who adjust eyeglasses without again cleansing their hands, have obtained results not much inferior to those of the most scrupulous followers of modified Listerism. After all, it must be remembered that antisepsis, or asepsis, is not a ritual but a means to an end, and perhaps the very men whom to-day we call careless, deserve the name no more than do those who have taught us that air—even the air of a crowded amphitheatre—may be admitted about a wound with impunity, and that the continuous antiseptic spray is not only useless but dangerous.

One after another have the idols of antiseptic surgery tottered beneath the blows of bacteriology. Bacteria have lived in dry iodoform; carbolic acid to be rapidly efficient in killing or paralyzing germs must be intolerably strong, and, *vice versa*, if tolerable, its solutions are practically useless save for extremely slow disinfection; we have seen mould grow on leather over which a hydro-naphthol solution had been spilled, and even corrosive sublimate solutions are now alleged to be resisted by bacteria rolled up in silk or catgut threads. In fact, boiling water and the actual flame are almost the only germicidal agents in which we may believe.

Why then has the antiseptic surgery of the past few years, based, as we are now informed, on exaggerated ideas of the efficacy of chemicals, and too often practiced inconsistently or negligently, yielded such magnificent results? Why is it that methods so utterly different in detail that the uninitiated would not dream of tracing them back to a common belief in the malevolent action of vegetable germs, have been in accord in leading to the prompt healing of wounds without suppuration? We can scarcely hold that sincerity of purpose would bring the same result from such varied modes of practice and must look for a common-place explanation. It would seem that the tests applied to antiseptic reagents by bacteriologists have been too rigorous. The bacteria experimented with have, for the most part, been taken from pure cultures, and have been abnormally abundant and virulent. The conservative element of phagocytosis has been lacking, and in many instances spore-bearing bacilli of exceptional resisting powers, and, fortunately, of considerable rarity, have been selected. It must be born in mind that bacteria are but peculiar kinds of weeds, a few hundred or thousand of which may do little harm and may even be choked out of existence by the phagocytes. Moreover, the ordinary septic germs are not very hardy plants and they are quite easily killed or at least reduced to insignificance by the chemicals which fail in the case of such vigorous exotics as the anthrax bacillus.

In general surgery the issue between asepsis and antisepsis is mostly a question of the surgeon and his surroundings. The man who has the habit of cleanliness —who keeps clean his own person, his instruments, his assistants, his nurses as well as his patients and surroundings—who has the time and patience to acquire cleanliness and who can control surroundings to an extent sufficient to maintain it, (nothing is more difficult than to be clean surgically speaking), such a one may well advocate the practice of asepsis to the ex-

clusion of chemical substitutes. But the every day practitioner who cannot control his surroundings, who is unable to avoid contact with contamination, who may be frequently and unexpectedly exposed to contagion and to the ordinary saprogenic and hypogenic germs, who must accept required assistance of the most unsatisfactory character, who has to combat dirt and ignorant relatives even more than disease, whose facilities and equipments are meagre and imperfect and who cannot maintain even if he can acquire cleanliness—it is well for such a one to reinforce his imperfect efforts at asepsis by any or all chemical agents he can bring to his aid. Asepsis is the ideal condition, antisepsis a means for attaining it.

## THE PYELITIS OF PREGNANCY.†

Ninay (*Le. Bull Mèd.* June 7, 1893) remarks that inflammation of the ureter and renal pelvis in the course of gestation has but slightly attracted the attention of physicians and obstetricians, either because it is an affection very rarely observed or rather because the signs and symptoms which accompany it have been unrecognized and reported as cystitis. The onset of the complication is variable. At times it produces much disturbance in the form of grave general symptoms with chills, vomiting, acute pains; again the progress is most insidious and tedious, the phenomena less accentuated, the pyelitis is added to an already existing nephritis and manifests itself under the title of this simple complication. Two patients are reported, as follows: the first a young woman of twenty-six, primipara at the eighth month of pregnancy. She was exposed to a cold spell of weather and at the same time became much fatigued by walking a long distance. In the evening she experienced a violent chill, followed by three others during the night. Her temperature rose to 40° C.; there was no vomiting, diarrhoea, nor cephalalgia, urine was scanty, there was but slight painful micturition, and the urine contained an abundance of pus, was acid, but there were no casts or blood corpuscles. At the same time there appeared an acute pain in the right flank and corresponding renal region. Pressure increased this pain, which prevented the patient from moving, so that she could scarcely turn herself in bed. Three days later after an instrumental labor she was delivered of a living child. Fever and pain persisted for several days, the urine remained purulent for a still longer period and convalescence was prolonged. The second patient presented a history and clinical course almost identical with this.

The principal symptoms of this condition of acute inflammation of the pelvis of the kidney are lateral abdominal pain over the renal region, radiating down the ureter and extending to the bladder, but slight trouble with micturition, indifference to pressure over the bladder, the capacity of which always remains considerable, the fever and general symptoms in proportion to the infection, and finally the presence in the urine of innumerable pus corpuscles. The predisposing causes are the congestive state, traumatism, and retention; the determining cause is microbic infection. The congestive state is not an additional circumstance; it is common to pregnancy and the puerperium. Retention is especially frequent during pregnancy, whilst contusions of the ureter are the exclusive consequences of the operations and traumatisms that accompany parturition. From the point of view of the predisposing causes there is a certain difference between the pyelitis that precedes delivery and that which follows. During pregnancy we observe to intervene the retention and urinary stasis that are determined by compression of the ureter in its pelvic course. This compression

† Translated for THE MEDICAL AND SURGICAL REPORTER, by W. A. N. Dorland, M.D.

only exists on the right side. It is the rule in this form of pyelitis, and if purulent pyelitis of the left side exists it is extremely rare and always consecutive to parturition. Its origin, moreover, is distinct; it is an extension from an already infected bladder. The infection which propagates itself by rising from the bladder affects indifferently either of the ureters.

Compression of the ureter was noticed in 1870, by Halbersma who regarded it as a favorable condition for the development puerperal eclampsia. But, long before him, Cruveilhier had drawn attention to the fact that increase of the lower uterine segment produced a compression of this canal, as observed upon the cadavers of pregnant women dead before delivery. The anatomical reason of this peculiarity is without doubt the usual inclination of the uterus to the right side, and as the iliac artery juts out more markedly on this side it becomes easy for the ureter to be compressed between this vessel and the presenting fetal part. The existence of general symptoms more or less grave, the presence of pus in the urine, show that there is present an infectious disease, because we may legitimately apply to pyelitis the precept that Guyon has indicated for cystitis; *there is no pyelitis without pus.*

The renal retention that results from the compression of the ureter is incapable of itself of provoking a persistant inflammation. The intervention of an infectious agent is necessary. The interesting researches of Reblaub have furnished us with some ideas as to the nature of this agent. He has observed constantly in the urine of patients with pyelitis, the *bacterium colli.* This habitual inhabitant of the intestine is not pathogenic under ordinary circumstances, but it may acquire virulent properties under the influence of course poorly defined, among which may be mentioned chilling, fatigue, errors of diet. If the colli bacillus become virulent, fixes itself upon the mucosa of the renal pelvis, it is because this place is modified and its soil has become favorable to the localization.

The progress of pyelitis occurring in the course of pregnancy varies; at times the effection is simple—rest will cure it; at other times the gravity of the general symptoms interrupts the pregnancy, and parturition puts an end to the symptoms. The diagnosis is, Vinay believes, nearly always easy. The progress is generally not very grave. Miscarriage may result in some cases, and after the emptying of the uterus the symptoms pass away. As regards treatment, in the benign forms, horizontal repose, baths, regimen, and proper hygiene will suffice to cause an amelioration if not a disappearance of the symptons. Emollient drinks in large quantities, and the use of milk in the form of a mixed diet to the amount of $1\frac{1}{2}$ to 2 liters daily may be added. Absolute milk diet will be necessary if a nephritis complicates the pyelitis. The employment of mineral waters is often of value; the best are the feebly alkaline waters, as the waters of Pouguer, Alet, and Vittel. Local vessicants, sinapsiams and subcutaneous injections of morphine are serviceable. If there should be sufficient gravity of the symtoms, menacing the life of the patient, labor may be induced.

## Abnormal Development of the Teeth, Forming Tumors of the Jaw.*

Dr. O. Hildebrand, of Göttingen, makes a further statement upon the case which he reported in 1889, in which the child of 12 years, who had been submitted to various operations, had been relieved of between 150 and 200 teeth of various sizes.

In July, 1891, patient had again presented itself at the Göttingen Surgical Clinic; both lower jaws were much thickened, as also the right upper jaw. On the whole there were found 17 teeth, part of them normally developed, others in an undeveloped condition; their position was deviated and irregular.

From the upper and lower jaw there were again some masses of teeth removed, which had the same confirmation as those formerly described, and presented about 150 teeth; aside from this, there were found two round glassy bodies about the size of two peas, which upon microscopical investigations showed themselves to consist of tooth structure. The construction of teeth in this patient will continue, in all probability, until the soft tissues have all reached their final development, which will include the epithelial structure of the teeth.—*Deutsch Ztschr. f. Chir.*, 35-5-6—93.

*Translated for The Medical and Surgical Reporter by Marie B. Werner, M. D.

## REMARKS UPON THE TECHNICAL CONSTRUCTION OF THE ANUS PRETERNATURALIS IN A CASE OF INOPERABLE CARCINOMA OF THE INTESTINE.

The author's (Helferich) method consists, in the above named classes, in

1–Laparotomy at the typical place of the left Iliac Fossa, the incision being made large enough to find the Aponeurosis of the oblique abdominal externis muscle. This is sufficiently divided to make it possible to form an artificial sphincter.

2–The Flexura Sigmoidea is drawn forward with the finger or with a hemastatic forceps.

3– In order to prevent the hernia of the intestines, the upper portion of the Flexura must be stretched slightly in its attachments, with a rubber drain previously surrounded by an iodoform gauze.

4–Consists of a secondary opening of the intestinal loop, three to six days after the first operation, no narcosis ; a spindle form piece is cut out of the loop.

The results obtained by the author have been on the whole very good, there having been a general increase of the patients' health after the operation.

In gastrotomy Helferich makes use of the rectus abdominis, which he splits parallel to the mucle fibre, in order to form the sphincter. The opening through perinæum muscles and skin is when united to the walls of the stomach which has been drawn forward ; it is united by catgut, and apex is fixed with silk sutures. The stomach is then opened, a relatively thick walled rubber drain is inserted and fixed into the wound of the stomach. Drains are tied with silk transversely over the abdominal wound.

The three cases operated upon were conspicuous by the prompt success of the operation, and above all, since then alimentation is continued without any difficulties.—*Deutsche Med. Wochen 1893.*

# ABSTRACTS.

## PAINFUL MICTURITION IN WOMEN.

In an admirable lecture upon this subject, Herman (*Provincial Medical Journal*, vol. xii., No. 138) states that about one-half the patients who consult a specialist for diseases of women complain of pain in passing water; but it is only the diseases which cause severe pain which require special treatment, so far as the urethra and bladder are concerned. All these cases of severe pain depend upon local diseases, which can only be discovered by direct examination. There are three places in which disease may exist occasioning this suffering,—namely, the *meatus urinarius*, the urethra, and the bladder. Pain in the *meatus urinarius* may be caused by *urethral caruncle*, by chronic congestion or suppurating cyst of the urethra, by abscess of the urethro-vaginal septum, or by a tender, congested condition of the urethral mucous membrane. Chronic congestion of the urethra is chiefly seen in pregnant women; the urethra is swollen and tender and feels like a thick cord. Not only the act of micturition, but sexual intercourse may occasion almost unbearable suffering.

The treatment for this condition is complete rest, cold sponging on the part, cold hip-baths, the use of vaginal astringent injections, one or two leeches applied by a glass leech-tube to the swollen and tender urethra, and gentle laxatives.

Chronic abscess of the urethra-vaginal septum is rare, and is characterized by a tense, hard, convex, bullous, very tender swelling between the urethra and vagina.

The treatment is evacuation. If there is a spot on the vaginal aspect of the swelling which is thin, and fluctuation is felt, the proper course would be to cut into this thin part. If there is no such spot the urethra should be dilated under an anæsthetic until the canal will admit the finger, and the purulent collection can be evacuated through the urethra.

Suppurating cysts of the urethra form a pouch communicating with this mucous canal by a narrow, somewhat valvular, opening; urine gets into the pouch, decomposes, and inflames the sac. On examination, a round, tender swelling is found in the urethro-vaginal septum, varying in size from that of a pea to that of a hen's egg. By pressure there will be voided either urine or urine and pus, sebacious matter, or a calcareous deposit, depending upon the nature of the cyst. These cysts do not run the course of an abscess, which gradually close up once an opening has been made for the escape of pus, but they continue indefinitely in the same state, alternately filling with pus and urine, and being partially emptied by pressure.

The treatment is excision of the whole or greater part of the cyst-wall. This is best accomplished by first laying open the cyst freely from the vagina. What is next to be done depends upon the skill of the operator. The cyst-wall should be dissected out and the raw surfaces brought in contact by means of either cat-gut or shotted sutures. If a portion of the cyst near the opening is left and the rest is closed, the object of the operation will nevertheless probably be obtained, for if the pouch is obliterated there will be no place in which the urine can be retained and decomposed, and therefore no inflammation. If the operator mistrusts his manipulative skill, it may be enough simply to open the cyst freely from the vagina, and then, by keeping the vaginal opening from closing by packing with lint or gauze, retention of fluid in the cyst will be prevented, the urethral opening may close, and then the cyst will be left with an opening only into the vagina. If no more urine gets into the cyst-cavity, inflammation will subside and no further symptoms will be exhibited.

If there be much inflammation of the cyst, of the urethra, or of the bladder, it may be well to make no attempt at closing the opening until such inflammation has been subdued by appropriate treatment. If the cyst is suppurative, or not open, or the urethral opening of an inflamed diverticulum has become closed, the condition cannot be distinguished from an abscess. When the pus-cavity has been opened, its cystic character will be inferred from its definite smooth fibrous wall. An abscess has not a thick fibrous wall. The inside of a diverticulum may be trabeculated, so that the origin of the pus-cavity cannot always be surely made out from the feel of the interior. If the cavity be an abscess, it will quickly fill up; if it does not quickly become obliterated, it should be treated as a cyst. In some cases the patient will complain of severe burning, cutting pain at each act of micturition, but the meatus will be found to be healthy, nor on palpation through the vagina can any area of inflammation be felt. On urethroscopic examination of the mucous membrane it will be found a vivid red or deep purple, appearing in patches or involving the whole mucous surface. Passage of the catheter is extremely painful.

The treatment is to apply some alterative to the diseased mucous membrane; the best, in the author's opinion, is iodoform. The application is most conveniently made by putting into the urethra a bougie made of iodoform and cacao butter. A little wool put between the labia will prevent the bougie from slipping out. In recent cases the use of three or four bougies will cure the patient. In cases of very long standing more prolonged treatment will be required. Nitrate of silver is also serviceable in this condition. In some cases application of nitric acid to the tender part is followed by relief. Dilatation of the urethra is also to be recommended. In some cases both the meatus and urethra are healthy, but on passing a bougie great pain is experienced as it enters the bladder. In these cases a urethroscopic examination will show either hyperæmia or fissure of the vesical neck, the symptoms of extreme pain on micturition persisting afterwards; also great frequency, and difficulty in emptying the bladder. Sometimes a little blood escapes with the urine. The urine is clear, and there is tenderness about the vesical neck. Direct examination shows the fissure as a small grayish ulceration, with red, inflamed edges at the vesical neck.

The treatment consist in dilatation of the uretha under anæsthesia ; this is best accomplished by meana of Hegar's dilatators until the urethra admits the finger. Temporary benefit always follows this procedure, and sometimes permanent cure. The objects to this treatment are that there is danger of septic infection of

the bladder and of permanent loss of control over the sphincter. Inconvenience rarely results unless dilatation is carried beyond the point necessary to admit the finger. In case dilatation is unsuccessful in relieving symptoms, vaginal cystotomy is indicated. To preform this operation a director should be introduced into the uretha and held exactly in the middle line. Open the bladder from the vagina by cutting upon the director. If the incision is exactly median, no important part can be wounded. To prevent this opening from closing, Greenhalgh's India-rubber stem may be employed, or the vesical mucous membrane may be sewed to the vagina on each side by a catgut stitch. All pain ceases at once, and if the artificial fistula is kept open long enough, the ulcer heals, and then the fistula can be closed and the patient remains well.

To minimize the discomfort of the artificial incontinence resulting from this operation, the patient should be kept upon a fracture-bed. The rest in bed is of itself beneficial. If nothing is done to prevent the healing of such an incision of the bladder, it soon either heals or contracts to a canal only large enough to admit a probe. As to how long this fistula should be kept open no rule can be given. If as the fistula heals symptoms return, the artificial opening should be again enlarged.

Baker's method of treating these cases is to keep the patients in bed for only a few days, then to fit them with a urinal, and allow them to get up and enjoy fresh air and exercise. The fistula is kept open for months, and is not closed until the interior of the bladder has ceased to be tender and, in case of cystitis, until all trace of pus or blood has disappeared from the urine. This, however, sacrifices the advantages of rest, and it has the discomfort of constant soiling of the clothing.—*Therapeutic Gaz.*

## THE CAUSE WHICH DETERMINES SEX.

In speaking on this subject before the Capital District Medical Society, the author states that he approaches it with an unaffected timidity and difference to open it for discussion.

I am thoroughly aware of the difficulties surrounding the matter, and more especially since all that may be, or can be, said will be largely of a speculative character.

There is one curious feature connected with the subject: it is also an incontrovertible fact, which has its weight in the consideration of this subject. I refer to the fact that—no matter what the cause, whether from battle or otherwise—whenever there is a large depletion of the male population, nature brings about an equilibrium by bringing a majority of males into the world. It matters not by what name you denominate the causes tending to this fact, one will necessarily conclude that it is divine,—a reason being, that a great preponderance of females and a scarcity of males would lead to social disaster and ruin. This is not exactly predestination, but a physiological process left partly to "chance;" but now, I hope, under the control of man.

The best state of society is found where the sexes assume about equal numbers. The apparently most natural and at the same time easy deduction is, that the sex is regulated by direct divine intervention. Granting this, the subject would be at rest: there remains nothing more to be said.

I have given the subject close attention, careful consideration, and diligent study; and, without arrogance, I think I have discovered the true theory.

That a great boon would result to humanity were this the case, there can be no doubt. Hereditary habits could be corrected, etc.; for the reason that female children are less likely to become victims of the various hereditary habits than male children. Along with this, however, would come the danger of an unequal proportion of the sexes.

There are, as far as I know, *four theories*, exclusive of divine interference, that have been advanced, none of which seem to be satisfactory.

1.—If conception takes place in the dark of the moon, the child will be a boy; if in the light of the moon, it will be a girl. This is too absurd for consideration.

2. All the eggs in one ovary are male eggs, and all in the other are female eggs. This cannot be accepted, as women have frequently given birth to both male and female children after one ovary had been extirpated.

3. If conception takes place before menstruation, the child will be a male, if after menstruation, a female. This is contradicted by the fact that male as well as female children have been born to women who were separated from their husbands either before or after menstruation.

4. If at the time of conception the sexual desire and passion is greater in the father, the child will be a female; and *vice versa*. This will not hold good, as many women who have never felt any satisfaction in sexual congress have given birth to both male and female children.

---

Let us now direct our attention to what I consider the true theory. In the stroma, or body of ovaries, are found 7,000 to 30,000 ovules or eggs, which ripen and mature, from one to six at a time, about once a month: one-half of these are male eggs, and will develop into male children; one-half female eggs, which will develop into female children. Ripening takes place alternately; first a male egg, next a female egg, etc.

That sounds very well, but the critic asks: Can you prove it? I think the following authentic and carefully-selected statistics, collected during the last three years, will establish the fact almost beyond controversy. I find one case where a young girl became pregnant at the first menstruation; the child was a male; two that became pregnant at the fourth menstruation, each bearing a female child; one that became pregnant at the 5th menstruation, the result a male child; 7 that became pregnant at the 10th menstruation, all bearing female children; 12 becoming pregnant at the 25th menstruation, all the children being males; one becoming pregnant at the 54th menstruation, a girl being the result. In case of twins, two eggs have ripened at a time if the children are of different sexes; if of the same sex, three eggs have ripened,—one failing to become impregnated. I have found three *corpora lutea* in a patient who had died of puerperal eclampsia after giving birth to two male children.

If a woman becomes pregnant at the next menstruation *after* giving birth to a male child, the offspring will be a female, and vice versa. I found six women who became pregnant at next menstruation after giving birth to a male child, and the result was a female offspring; one case where a woman became pregnant at 2d menstruation after, and the child was a male, 10 cases at 5th, and 8 cases at 6th, with the expected result. (*)

But what about a *hermaphrodite?* In my opinion, there is no such condition; it must be either one sex or the other. The supposed penis is either an enlarged clitoris or a malformation.

—*Amer. Med.-Surg. Bulletin.*

---

### The Use of Thiol in the Treatment of Burns.

Bidder (*Archiv fur klinishe Chirurgie*, Band xliii., 1892) says that in treating burns a dressing should be selected that does not require frequent changing.

Thiol may be used in two forms, the fluid and the powder. Its action on the burnt surface is:

(1) As a drying substance.
(2) Relieves the pain.
(3) Hardens the new skin.
(4) Hinders the growth of all micro-organisms that may have gained entrance to the wounded parts.

---

### Treatment of Comedones.

Dr. H. Von Hebra (*Hospitals-Tidende*, No. 11, 1893) prescibes the two following solutions in the treatment of blackheads:

1. ℞ Rosewater, Alcohol, Glycerine, āā gms. 10 (ʒijss)
Borax gms. 5 (ʒj¼)
Shaking before using.

2. ℞ Green soap gms. 40 (ʒj¼)
Spir. lavender gms. 10 (ʒijss)
Alcohol gms. 80 (ʒijss)
Every morning wash the skin with No. 1, and then rub in No. 2. Then wash off with warm water.

---

### Naso-Pharnygeal Catarrh of Nurslings.

Dr. Neumann (*La Semaine Medicale*, No. 33, 1892) has obtained excellent results in the treatment of naso-pharnygeal catarrh, so severe even as to interfere with nursing, by employment of the following solution:

℞ Sulphate of zinc gms. 0.10 (grs. jss)
Water gms. 15 (ʒiv)
Instill a few drops of this solution into each nostril several times a day.

---

* The author's theory *fails*, however, to explain the fact—quoted by himself—of the preponderance of male births in a region largely depopulated of males, and vice versa; unless he brings the 4th of the *current* theories, above cited, to his aid: to the effect that *fecundation*, under a scarcity of males, will more readily occur on the male ova, on account of the more intensive orgasm on the woman's part.—[Ed.]

# SELECTED FORMULÆ.

### Treatment of Hyperidrosis.

Several new formulæ for the treatment of sweating hands and feet have been recently introduced. The following are among the best of them:

The *Monatshefle fur Prak. Dermat.* recommends an alcoholic solution of borac acid, borax, and salicylic acid, as follows:

℞
Boric acid..... ℥j
Borax
Salicylic acid.....āā ℥ij
Alcohol ..... ℥vj

Mix and make a solution, with which rub the palms of the hands or soles of the feet thrice daily.

The *Centralblatt fur die Gesammate Therapie* recommends the following mixed treatment:

℞
Beta napthol..... ℥ij
Glycerin..... ℥ss
Alcohol ..... ℥v

Mix and dissolve. Use as a wash to the parts affected twice daily; dry, and apply the following powder:

℞
Beta naphthol..... gr. xxiv
Starch..... ℥v

M. Pulverize and mix.

—*Ex.*

---

BROMIDISM may be prevented by combining an intestinal antiseptic with each dose of the bromide salt as follows:

℞
Potassii bromidi..... gr. xxx
Beta naphthol ..... gr. xx
Sodii salicylat..... gr. x

M.

---

EMBALMING is accomplished by a new process attributed to Dubois, a Frenchman, in which the body is dehydrated by means of amylic alcohol or nitric ether, or a mixture of both injected in the usual way. It is placed in an air-tight chamber and surrounded with calcium chloride and its entire surface is eventually coated with a solution composed of balsam tolu and benzoin in equal parts in ten times their weight of either. According to the *Br. and Col. Dr.*, the body is said to retain its natural appearance.

---

### Brown Leather Polish.

℞
Annatto..... ½ ounce
Catechu..... 1 ounce
Gamboge ..... ½ ounce
Gum acacia ..... ½ ounce
Hydrochloric acid..... 1 fluidounce
Water..... 2 pints

—*Bulletin of Pharmacy.*

---

PROF. HARE gives the following prescription as useful in the sub-acute stages of bronchitis :

℞
Vini ipecac ..... f℥j
Tinct scillæ ..... f℥ij
Syrup tolutan ..... f℥v
Aquæ destillat..... f℥j

M. Sig.—Teaspoonful every three hours.

### Eczema of the Vulva.

Lusch employs the following :

℞
Tincturæ opii } .....āā gms. 8
Sodii bicarbonatis }
Potassi bicarbonatis..... gms. 4
Glycerini ..... gms. 6
Aquæ destil..... gms. 206

---

PROF. GRAHAM is of the opinion that the prognosis of hereditary syphilis in children will depend to a great extent on the length of time that elapses between the birth and the appearance of the eruption. The sooner the eruption appears after birth, the better will the prognosis be.

---

### Tape worm.

℞
Pelleturin sulph ..... gr. vi-viiss.
Pulv. acid tannic ..... gr. viiss.
Syr. simpl ..... ℥ij

M. Sig.—Take the above the following morning before breakfast. Fifteen minutes after take two tablespoonfuls of castor oil.

—*Labbe, Ex.*

---

### Acne.

Dr. G. T. Elliot prescribes :

℞
Zinc sulph } .....āā grs. v-xxx
Potass. sulphuret. }
Aquæ rosae ..... ℥j
Sulphuris praecip ..... grs. xx-xl

M. Sig.—Apply to face three times a day.

---

PROF. KEEN gives the following formula for Morton's fluid ; useful where absorption is required :

℞
Iodinii ..... gr. x
Potassi iodidi ..... gr. xxx
Glycerini ..... f℥j

M. Sig.—Use locally.

---

### Liquid Spice Plaster.

Med. Bulletin.

Capsicum,
Cloves,
Cinnamon,
Ginger, of each, 4 drs

Exhaust with stronger alcohol, evaporate to 4 ozs. and add to a solution of

Rosin..... 9 ozs to 2 lbs.
Venice turpentine ..... 7 ozs.
Alcohol (95 per cent.)..... 12 ozs.

Spread with a camel's hair brush on paper covered with muslin, and apply in lumbago, muscular rheumatism pain in chest, etc., over place of pain.

---

### A Deodorizer for Iodoform.

The following (*Norsk Magazin fur Lægevidenskaben*, No. 3, 1893) is recommended :

℞
Iodoform ..... gms. 187 (℥vj)
Carbolic acid..... gms. 1 (gtts. xv)
Oil of peppermint.... gms. 2 (gtts.xxx)

# CURRENT LITERATURE REVIEWED.

THE AMERICAN JOURNAL OF OBSTETRICS for July. Dr. J. Whitridge Williams contributes an article on

**Calcified Tumors of the Ovary.**

He reports two cases of the disease and one case of calcified corpus luteum. He also says that, in several instances, the tumors sent him for examination as osteoma of the ovary proved to be simply calcified fibromata and in one instance, what was supposed to be a nodule of true bone was found to be a calcified corpus luteum. He further says that while true osseous tumors also occur in the ovary they are even more rare than calcified tumors. Of course, in speaking of calcified tumors of the ovary, all growths which are connected with dermoid tumors are excluded. The process of calcification is always preceded by more or less necrosis of the affected part. All forms of necrosis do not lead to calcification but particularly coagulation necrosis and then only under certain conditions. The general law in regard to the production of calcareous deposits seems to be coagulation necrosis to which some supply of blood or lymph is admitted. The clinical history of calcified tumors of the ovary does not offer any distinguishing features from other solid tumors of the ovary. They rarely attain great size; in one or two cases there was marked dysmenorrhœa; in several cases there was marked uterine hemorrhage, which ceased after the removal of the growths. It is impossible to distinguish the condition under consideration from other hard tumors of the ovary; when the diagnosis has by any possibility been made, the removal of the tumor is indicated.

Dr. Charles M. Green contributes a paper on

**Puerperal Eclampsia,**

giving the results in the Boston Lying-in-Hospital during the last eight years. As to the treatment of ante-partum eclampsia: Ether was used to control the convulsion and he believes that it is as safe as chloroform for that purpose. Chloral hydrate by the rectum was used as a sedative between the attacks. Morphia is not approved of, as in some cases it seemed to cause restlessness. The action of the skin is excited by means of the hot bath, hot air bath, etc., and for drugs, pilocarpin in gr. $\frac{1}{8}$ doses, guarded by stimulants. If the skin does not act readily, the bowels are moved by croton oil or elaterium. Cream of tartar water and digitalis are used as diuretics. Venesection has not been resorted to. When it becomes necessary to deliver the patient rapidly, manual dilatation of the cervix is preferred to dilators or hydrostasic bags. Podalic version and manual extraction are preferred to forceps, unless the head is engaged. When the attack occurs during labor, it is the practice to deliver as speedily as possible. After delivery, chief reliance is placed on chloral, pilocarpin, hot bathing or the hot air bath, mild diuretics, and necessary stimulation. Post-partum eclampsia is treated, in general, in the same manner as in inter-partum cases after the labor has been completed. If symptoms of threatening convulsions appear during delivery, the labor is not hastened, if progressing normally, and treatment is directed toward allaying nervous symptoms and mildly stimulating the function of the kidney. The paper includes tables showing the number of cases treated and the results.

Dr. Reuben Peterson discusses the subject of

**Tubal and Peritoneal Tuberculosis,**

reporting four cases. He comes to the following conclusions:

1. Tubal tuberculosis, either alone or with coexisting involvement of the peritoneum, is far more frequent in occurrence than is commonly supposed.
2. Early operative interference is indicated in the presence of either tubal or peritoneal tuberculosis, as a safeguard against the further extension of the disease.
3. All cases of tubal or peritoneal tuberculosis subjected to a laparotomy should be drained, and whenever practicable, the iodoform gauze drain should be employed.

Dr. George M. Edebohls contributes a paper on

**The Operative Treatment of Complete Prolapsus Uteri et Vaginæ.**

The author states that, until such time as it can be shown that the results acheived by total extirpation of the uterus for prolapsus are better and more lasting, as well as that the operation is no more dangerous than the rival procedure, he will adhere to ventrofixation of the uterus combined with the necessary plastic operations as the rule, practicing total extirpation only on exceptional indications, as:

1. A uterus so large and heavy as that it cannot be reduced to an approximately normal size and weight by amputation of the cervix.
2. A uterus presenting either positive evidence or strong suspicion of malignant disease.
3. A uterus with appendages so diseased that the condition of ovaries and tubes calls for their removal, apart from other considerations.

The author would also lay it down as an axiom that whenever the uterus is preserved in prolapsus operations it should be securely ventrofixated. The paper also includes a table of the twelve cases operated on by the author.

Dr. A. F. A. King reports a case of

**Labor Obstructed by Ovarian Tumor.**

In regard to treatment in these cases: The author is of the opinion that when the tumor is large and below the pelvic brim, and cannot be pushed back to make room for the child, the only modes of proceeding available

would seem to be : [1] abdominal section of the mother, [2] mutilation of the child, or [3] puncture of the tumor. Playfair's tables give the best results from puncture of the cyst. In cases where the tumor is smaller and capable of being pushed up out of the way of the child, it becomes an interesting question whether such a method of treatment, with its well known risks, would be better than emptying the tumor by puncture.

Dr. S. C. Gordon discusses the

**Dangers and Complications of Uterine Fbroids.**

The conclusions arrived at are:

1. Uterine fibroids are always more or less troublesome, and in a majority of cases produce a state of chronic invalidism.

2. In a large percentage of cases they are complicated with excessive hemorrhages, peritonitis, salpingitis, and ovaritis, with purulent collections and adhesions, producing continual suffering.

3. Many of them do not cease growing at the menopause, but increase.

4. Many undergo degeneration, either calcareous, cystic, or malignant.

5. Hysterectomy is not a very dangerous operation if made in the early history of the case—no more so than ovariotomy.

6. In addition to the saving of life, it relieves (in nearly all the cases) the woman from the life of invalidism.

Dr. Charles P. Noble contributes a paper on "The Question of Operation in Cases of Chronic Ovaritis." The conclusion arrived at is that operation should be performed if continued well-directed treatment does not benefit the patient. Particularly is this the case with those women who are dependent on their own labor for support. The author also urges that all ovaries removed because of chronic ovaritis, should be submitted to a competent patholgist for careful study, that new light many be thrown upon these conditions.

Dr. H. Marion Sims contributes a paper on "Hystero-epilepsy," reporting seven cases cured of the disease by surgical measures.

Dr. Frank A. Stahl, in a paper on "Digital Curetting of the Puerperal Uterus," shows very clearly the great advantage of the finger over any form of instrument in these conditions.

The other papers in the current issue are: "Vaginal Enterocele in Pregnancy and Labor," by Dr. Barton C. Hirst; "The Abdominal Brain in Gynecology: Its Reflex and Rythm," by Dr. F. Byron Robinson, in which the author shows the part which the sympathetic system plays in abdominal diseases. The remaining paper is by Dr. Thad. A. Reamy on "Membranous Dysmenorrhœa."

---

THE VIRGINIA MEDICAL MONTHLY

for July.

Dr. J. R. Buist contributes a paper on

**The Management of Retroflexio Uteri,**

in which he has come to the following conclusions:

1. We believe that in the large majority of cases the predominant morbid state allowing of retroflexion is to be found in the uterus itself; a diseased state of this organ is the primum mobile of the trouble.

2. Next, an extension of the metritic disease to the tubes, ovaries, and peritoneum is the most usual sequence of changes, and the relaxation of ligamentous supports the last.

3. The skilled gynecologist will treat the complications first, resort to pessaries last, and when opportunity offers, or the symptoms severe enough, select some one of the surgical methods of fixation.

Dr. E. M. Magruder in a paper on

**Aneurism of the Vertebral Artery—Its Successful Treatment,**

gives the following:

1. Vertebral aneurism is very rare, and its treatment has been exceedingly unsuccessful.

2. The causes of the lack of success are (1) inaccessible situation and (2) errors in diagnosis.

3. Of the twenty-eight cases (the author's the twenty-eighth) mentioned in the paper, three were cured and twenty-five perished.

4. Of the three cases cured, one was treated by cold and direct pressure, one by enlarging the original wound and using a styptic and bandage, and one (the author's) by a combination of incision, evacuation, packing and compression.

5. Vertebral aneurism can be safely laid open and treated, the only danger being immediate hemorrhage. The requisites for success are quickness and perfect asepsis.

6 Treatment by incision, evacuation, packing, and compression is the safest, easiest and surest method yet devised for vertebral aneurism, and is bound to succeed.

Dr. Mathew M. Smith in a paper on

**Hypnotism,**

advises that the use of this agent be limited to graduates in medicine. Even then it should be confined to its legitimate uses in the treatment of disease. As to the conditions that are cured or benefitted by hypnotism, the author believes that all pains that have no antomatical lesion, as headaches, ovarian, rheumatic and neuralgic pains, sleeplessness and hysterical conditions, and many disturbances of menstruation, alcohol, opium, and tobacco habits may be cured by its use. Neurasthenia, stammering, and nervous disorders of sight are benefitted by it. It may be used in minor surgery and labor to diminish pain. In treatment, many sittings may be necessary in order to get the beneficial results desired. Some physicians will have much better success than others with its use, just as some surgeons have a more skillful use of the knife than others.

Dr. W. R. Pryor contributes a paper on the "Treatment of Sterility." The author believes that, in the majority of cases, the endometrium is at fault and advises the dilatation of the cervix followed by a through curetting of the entire endometrium and packing with iodoform gauze. The author reports several cases in which the above treatment was followed by conception in a short time.

Dr. John S. Hughson advocates, in a paper on "The Treatment of Puerperal Convul-

sions," the use of large hypodermics of morphia to control the convulsion.

Dr. R. A. Patterson contributes a paper on "The Treatment of Diphtheria." The author advocates the use of a mixture of potassium chlorate, dilute muriatic acid, tincture of the chloride of iron and water, internally, followed by the application to the throat of a mixture containing one ounce of fluid extract of pinus canadensis and ten to fifteen drops of phenic acid.

Dr. John N. D. Cloud in a paper on "Malarial Hæmaturia," cautions against the use of quinine until the hemorrhage has subsided and the skin has regained its natural color.

Under "Clinical Reports," Dr. A. B. Pierce reports a case of ovarian tumor which has been tapped nineteen times.

Dr. John Dunn reports a "Case of Complete Bony occulsion of One Side of the Nose."

Other papers in this issue are: "Purulent Puerperal Peritonitis," by Dr. Virginius W. Harrison; "Reform Needed as to Medical Expert Testimony," by Dr. William B. St. John; "A Few Facts in the History of Abdominal Surgery" by Dr. Anne Walter; "Organic Syphilis," by Dr. Henry Robbins; and "What the General Practitioner Should Know About Diseases of the Eye" by Dr. Frank Trester Smith.

# PERISCOPE.

## MEDICINE.

### Terpene Hydrate in Bronchial Catarrh.

Dr. Wm. Murrell (*Med. Age*) says:

I am desirous once more of calling attention to the value of terpene hydrate in the treatment of affections of the bronchial and nasal mucous membranes. Its properties have been well known for many years, but in this country it has never been a popular remedy, and its claims seem to have been overlooked in favor of pure terebene and other similar compounds. It is a hydrate of turpentine, and is made by treating oil of turpentine with nitric acid and alcohol. It is a solid, and has somewhat the appearance of chloral hydrate. Its odor, which is slight, resembles that of pure terebene. The great difficulty in the way of its administration is that it is practically insoluble in water. It is usually said to dissolve in alcohol in the proportion of 1 in 10, but many specimens are far less soluble. On the Continent, where it enjoys a high reputation in the treatment of bronchial affections, it is used as a popular remedy in the form of an elixir. For some months past I have prescribed it in a solution containing five grains to the half-ounce, made up with simple elixir and flavored either with tincture of Virginia prune and syrup of tar or with aqua laurocerasi. For patients who cannot take sugar the elixir may be made with saccharine. Terpene not only relieves cough and lessens bronchial secretion, but is a diuretic, and has been used with advantage in neuralgia.

### Ichthyol in the Treatment of Erysipelas.

Glinsky states that during the last four years he has tried ichthyol with great succes in one hundred and twenty-eight cases of erysipelas. He concludes that this drug is decidedly the best means of all yet proposed for the treatment of this disease. It rapidly arrests the spread of the morbid process and reduces the average duration of the disease down to two or three days. The method is of the greatest value in all cases in which cardiac weakness, due to fatty degeneration of the heart, is present in patients with nephritis.—*Zemsky Wratsch*, 1892, Nos. 39 and 40.

### Chloride of Iron in Diphtheria.

Drs. Hubner and Rosenthal (*Munich Med. Woch.*) in two separate communications speak enthusiastically of the results of treating diphtheria by means of the chloride of iron. Hubner applied it locally in a 1.1 or 1.5 solution by means of a swab or brush, two or three times a day; Rosenthal, internally, in a 20 per cent. solution with glycerine as a corrigiens, a teaspoonful to a tablespoonful every hour. The results with both were astonishingly good.

### The Condition of the Spinal Ganglia in Tabes Dorsalis.

R. Wollenberg states that it is still a mooted question whether the seat of the primary changes in tabes dorsalis is in the spinal cord or outside of it. It is true that changes in the peripheral nerves and spinal ganglia have been frequently discribed, without its being possible, however, to determine their true pathogenic importance. In fourteen cases of tabes, Wollenberg has made examinations with regard to this point, with the following results: In the spinal ganglia, in all the cases examined, not only the nerve-fibres and the interstitial connective tissue, but also the ganglion-cells themselves were found to have undergone pathological changes. The excess of pigment and the shriveled condition of the cells can, of course, not be considered as a sure indication of disease; but this is not the case with the opacity of the protoplasm, which is always present, and with the agglutination of the cells, which may, undoubtedly, be regarded as typical of a pathological process. Although it is thus proven that in tabes the spinal ganglia present pathological changes in all their elementary parts,

yet these changes of the ganglion-cells may be regarded as insignificant in comparison to those occuring in the nerve-fibres and in the interstitial connective tissue.

We cannot, therefore, assume that tabes originates in the spinal ganglia, nor that the latter are the primary seat of the trouble; it is most probable that the changes occuring in the ganglionic cells of the spinal ganglia are only of a secondary nature, and are induced by a perineuritis developing in the region of the spinal-cord process and gradually involving the nerve-elements (first the nerve-fibres, then the ganglionic), cells and inducing atrophy.—*Archiv fur Psychiatrie*, vol. xxiv.

### Arsenical Neuritis.

Osler (*Montreal Med. Jour.*) relates a case to show that long continuance of full therapeutic doses of arsenic may lead to the development of peripheral neuritis. The patient was a Pole, suffering from Hodgkin's disease, affecting the cervical, axillary, and inguinal glands. During a period of seventy-five days he took ℥iv, ℥j, ♏ xviii of the liquor potassæ arsenitis, equivalent to sixteen and one-half grains of arsenious acid. The dose, for the greater part of the time, with some intermissions owing to diarrhœa, was ♏ xv three times a day. Increased pigmentation of the skin was noticed at an early period of the treatment, and, after about seven weeks, it was noticed that the muscles of the upper and lower limbs were tender to the touch, and that he walked stiffly. The knee-jerks which were then present had disappeared in another fortnight, and he was scarcely able to walk at all. The muscular power of the arms was diminished. The excitability of the muscles of the legs to both currents was diminished, and A.C.C. was equal to, if not greater than, K.C.C. Osler observes that idiosyncrasy must play a part in the production of arsenical neuritis, which is very rarely produced by therapeutic doses. He had only once before met with a case which raised the suspicion of neuritis, though he has been in the habit of treating pernicious anæmia, Hodgkin's disease, and chorea minor with arsenic, pushing the drug until its physiological effects were produced—itching of the skin, slight œdema, vomiting, or diarrhœa.

## SURGERY.

### Removal of the Seminal Vesicles.

Since Ullman removed both seminal vesicles for tuberculous disease, by Zuckerkandl's method—which consists in exposing the prostate and base of the bladder, by dividing the anterior attachments of the rectum and then freeing it from the prostate and lower part of the bladder—Roux has reported tw cases in which for tuberculous disease he has removed one seminal vesicle together with the spermatic cord and testicle of the same side through a lateral perineal incision, reaching the vesicle by a dissection carried upward between the prostate and the rectum.

Dr. George W. Gay, of Boston, in May, 1891, removed the right seminal vesicle, through a lateral perineal incision (similar to that practiced by Roux), for cancerous disease thought to be primary in the vesicle. Six months later the wound, which had healed well, reopened; the examination revealed a hard mass, about the size and shape of the forefinger, in the site of the seminal vesicle which had been removed.

Villeneuve reports a case in which he removed one seminal vesicle by exposing the spermatic cord outside the inguinal canal, and by freeing and pulling on the cord until the seminal vesicle was sufficiently brought down to be reached and excised.—*Boston Med. and Surg. Jour.*

### Prostatectomy.

The question of the advisability of this operation was lately brought before the profession by Mr. Buckstone Brown, who recommended the operation when a patient had to use a catheter every 2 hours, and life was a burden in consequence. He quoted the case of a gentleman, æt. 72 years, on whom he had operated a year ago for a small stone and finding the prostrate much enlarged he had removed two ounces of the gland; the patient can now pass all his water without requiring the use of a catheter. The general feeling of the society was that the supra-pubic method was the best, and that the gland should only be removed when obviously projecting into the bladder cavity. Bleeding is the worst feature of the operation, and can best be prevented by using special small toothed forceps which crush as well as remove the gland. All agreed that there was a considerable risk in the operation.—*Calcutta Med. Rep.*

### Pneumonectomy.

It was briefly stated in the *British Med. Journal* of February 25, that Dr. Lowson, of Hull, had operated on a case of tuberculous disease of the lung by removing the right apex, to which the disease was limited. We are glad to learn that the patient bore the operation well, and was able to get up for a short time in the third week; she was then eating well and had no pain. The operation was commenced by the removal of the anterior third of the second and third ribs; the parietal layer of the pleura was opened and the apex of the lung was pulled out after separating a number of extensive adhesions; the diseased apex was then transfixed with a needle and strong silk, firmly tied and removed. The sudden development of pneumothorax gave very little trouble and oxygen, which was at hand, was not needed. The respirations were never more than 44, and dropped in a day or two to 32, and soon after to 24; the pulse showed a similar elevation and decline. The highest temperature was

101.8°; this occurred in the second week and lasted five or six days, with complete morning remissions. The wound was quite healed by the end of the third week. The after history of this patient will be watched with much interest.—*British Med. Journal.*

## GYNECOLOGY.

### Noble (C. T.) on Certain Problems in Abdominal Surgery; Based on One Hundred Celiotomies.

The paper is an elaboration along the lines indicated in the following extracts:

The essentials of success in abdominal surgery are:

1. Early operation.
2. Careful preparation of the patient, with especial reference to stimulating the emunctories and to securing asepsis of the abdominal wall.
3. An aseptic operating room.
4. Aseptic hands and instruments for the surgeon.
5. As great rapidity in operating as is compatible with careful, thorough work.
6. Irrigation and drainage in septic cases.
7. Careful after-treatment, embracing especially the withholding of fluids for about forty-eight hours, early purgation and at least three weeks' confinement to bed.

Regarding the question of drainage the author says that the better results obtained at present without drainage, as compared with the results of ten years ago, is explained by five facts:

1. Surgeons do cleaner work; they are more aseptic than formerly.
2. They have better means for securing hemostasis.
3. They do not use irritating chemical antiseptic solutions in the peritoneal cavity.
4. They deprive their patients of water for forty-eight hours after operation, thus producing systematic thirst and bringing about the absorption of serum from the peritoneal cavity.
5. They purge early and freely on the first sign of peritoneal irritation.

He believes that the use of a drainage tube may cause hernia, and that it may prove an open door for infection. A carefully compiled table of cases closes this sensible article. —*Am. Jour. Obstet.*

### Vaginitis from Bestiality.

The patient (*Weekly Med. Rev.*) was "a smart, pretty, well educated" twenty-six-year-old country girl, who was found to be suffering from a profuse, thick, sticky, greenish yellow vaginal discharge of an extremely offensive odor, completely gluing the parts together. The discharge had been present for about a week, coming on suddenly. After washing the external genitals and opening the labia three rents were discovered, one through the fourchette and two through the left nymphæ. The vagina was found to be excessively congested and covered with bleeding points on the least irritation. Gonorrhœa was the presumptive diagnosis, but coitus was denied, albeit menstruation was stopped, and the patient was terribly perturbed about pregnancy. Under pressure, she confessed that one day she was playing with the genitals of a large dog. She became excited and thought she would have slight connection with him, but after the dog had made an entrance she was unable to free herself from him, as he clasped her so firmly with his fore legs. The penis soon became so swollen the dog could not free himself, and for more than an hour she made the most persistent efforts to do so, and finally making the ruptures before spoken of, and followed immediately by the discharges and inflammation. She was given the usual treatment for gonorrhœa, enjoining rest and soothing treatment until inflammation had subsided, since which time every kind of injection and treatment, applied both to the vagina and uterus, has failed to cure the discharge, pus cells being still abundant in the discharge; menstruation is normal. There was reason to suspect that the bestiality continued. The case is not unique, as Dr. I. C. Rosse (*Va. Med. Monthly*) reports that a young white single woman was surprised copulating with a large mastiff, whose endeavors to release himself caused fatal vaginal hemorrhage. The bony structures of the dog's penis, and the reversal attempted after completion of the canine sexual act, would be very likely to inflict wounds of the kind described in the first case.—*Medical Standard.*

### Gonorrhœal Infection of the Mucous Membrane of the Mouth in New-Borne Infants.

From the study of five cases of gonorrhœal infection of the mouth in the *Konigsberg Obsterical Clinic*, Dr. Rosinsky has drawn the following picture of the disease: Without preceding inflammatory redness, a white discoloration appears upon the anterior two-thirds of the tongue, the tongue, the plaques of Bednar, the hamulus pterygoideus, and along the ligamentum pterygomandibularum in the lower jaw, finally upon the front parts of the gums. After twenty-four to thirty-six hours the color becomes yellow. The patches elevate themselves plateau-like over the surrounding tissues, and their surfaces are raw. The superficial epithelium forms with extravasated pus cells, a thick layer, resembling the scrapings from the cut surface of a septic spleen. On the third day the regeneration of the epithelium begins; this is marked by an inflammatory redness around the edge of the patch. Healing follows without treatment, in an ideal manner, no trace of scar or discoloration remaining. From the microscopical examination of some excised tissue, Rosinsky has gleaned the following: The gonococci were never found, in stained sections, intra-cellular. They were seldom found intra-cellular in the superfical flakes.

Gonococci cannot penetrate into the body of healthy, living cells; they accomplish this only when the single cells are cut off from the conditions of life. In the connective tissue gonococci invasion was found. Rosinsky believes this to be typical pure gonorrhœal inflammation of the mucous membrane. The relatively infrequent gonorrhœal inflammation of the mucous membrane of the mouth in adults, in contradistinction to infants, he believes to be due to the tenderness of the epithelium of the mouth in the new-born.—*Annals of Gynecology.*

---

A STUDY of the effects of removing the ovaries shows that for some time there are menstrual molimina and the ordinary signs of the climacteric appear. The deposit of fat in the abdominal walls, buttocks and other parts of the body is attributed not to excess of nutrition but to vaso-motor changes. When the uterus is removed and the ovaries left behind the latter do not atrophy, as has been claimed, but subsequent autopsies have shown them unchanged in size and containing Graafian follicles ripening or breaking.—*Northwestern Lancet.*

---

### Supra-pubic Lithotomy.

Lawson tait thus describes the *technique* of this operation: "I make use of no precautionary measures or preparatory steps. I neither pack the rectum nor distend the bladder. I stand on the left of my patient and cut upward two inches and a half, starting immediately over the ridge of the pubic arch, exposing the tendon at one sweep. I then cut the tendon transversely over about one inch close to the bone, and cut it centrally for an inch and a half. I then pass my left forefinger between the bladder and pubic arch and follow it with a pair of forceps. I gently rend the tissue till I can feel bladder wall. This can easily be detemrined by its peculiar feeling, and by the fact that once the forceps grip it they hold, and they do not hold merely cellular tissues. Having fixed one pair, I then fix another close to them. My assistant takes them and gently pulls them apart, as in abdominal section; a notch of the knife follows, and a rush of water declares the road into the bladder for the forefinger to be open. The rest is all finger work, and consists as in abdominal sections of a gentle, but firm extension of the opening into the bladder, till the lithotomy forceps can follow it. All my cases have recovered without complications, and though up to the present I have used a glass drainage tube, I am of the opinion that this will prove an unecessary precaution, and that it will be safe to close the bladder by deep sutures."—*Lancet.*

---

### Fecal Fistula following Hernia—Closure by Resection of Intestine.

At the London Hospital Mr. Frederick Treves recently operated on a boy, æt. 16 years, who, six months ago, had been operated on for hernia. Probably the intestine was gangrenous, as it had been left in the wound, and a double fecal fistula resulted. The double opening in the intestine was freely exposed, the gut drawn out, and three inches of the ileum were removed. The ends were approximated by Lembert's suture.—*Med. Press and Circular.*

---

## ARMY AND NAVY.

U. S. ARMY FROM JULY 9, 1893, TO JULY 15, 1893.

The order assigning Captain Freeman V. Walker, Assistant Surgeon, to temporary duty at Fort Trumbull, Conn., is so amended as to relieve him from future duty at Fort D. A. Russell, Wyoming, and to assign hin to station at Fort Trumbull, Conn., until further orders.

1st Lieut., Charles F. Mason, Assistant Surgeon, July 2, 1893, promoted to be Assistant Surgeon, with the rank of Captain.

Major James P. Kimball, Surgeon, is relieved from duty at Fort Clark, Texas, to take effect at the expiration of his sick leave of absence, and ordered to Fort Marcy, New Mexico, for duty.

Major William H. Gardener, Surgeon, on being relieved by Major Woodruff, is ordered to duty as Attending Surgeon and examiner of Recruits at Steadgrs, Dept. of Dakota, St. Paul, Minn., relieving Capt. Walter Reed, Assistant Surgeon, U. S. Army.

Capt. Reed, upon being relieved by Major Gardner, is ordered to report to the Surgeon General at Washington, D. C., for duty as curator of the Army Medical Museum, and as professor of clinical and sanitary microscopy in the Army Medical School.

Captain William H. Corbusier, Assistant Surgeon is relieved from duty at Fort Wayne, Mich., and ordered to Fort Supply, Indian Territory, for duty, relieving Major Paul R. Brown. Major Brown on being relieved by Captain Corbusier is ordered to Fort Hamilton, N. Y., relieving Major Ezra Woodruff, Surgeon Major Woodruff on being relieved by Major Brown is ordered to Fort Keogh, Montana, for duty, relieving Major William H. Gardner, Surgeon.

Pharmaceutical Products of the Farbenfabriken vorm Friedr Bayer & Co.

**Phenacetine-Bayer**

ANTIPYRETIC and ANALGESIC; Prompt, safe and effective in Fever, Influenza, Rheumatism, Neuralgia, Pneumonia, Cephalalgia and all forms of pain.

Phenacetine is given in doses of 2½ to 10 grains, 3 or 4 times daily. It does not depress the heart.

Phenacetine is supplied in ounces, also in tablets and pills, alone and with Salophen, Sulfonal, etc.

**Sulfonal-Bayer**

HYPNOTIC and SEDATIVE; Indicated in all the Insomnias including those of insanity and the Neuroses; Causes no nervous or gastric disturbances. Must be given as directed.

The dose of Sulfonal varies from 15 to 45 grains; It should be given an hour or two before bedtime.

Sulfonal is supplied in ounces, tablets and pills; also in tablets in combination with Phenacetine.

*Other Farbenfabriken Products:*

**Salophen, Trional, Aristol, Losophan, Piperazine-Bayer, Europhen.**

*New descriptive Pamphlets on these Preparations mailed by*

# POST-OPERATIVE SEQUELÆ OF PELVIC AND ABDOMINAL SURGERY.*

JOSEPH PRICE, A.M., M.D., The Preston Retreat, Philadelphia.

The occasion and the peculiar auspices under which I appear here can scarcely fail to be to me somewhat embarrassing. I cannot avoid a feeling of inadequacy for a work which on account of its momentous importance should be well done. It may be claimed that all has been said; then what I say, I only throw in as confirmatory of that which is accepted as complete. That all has been said and the best done is a shallow assumption. We are just beginning to talk and that but stammeringly—and as yet much of our surgery is bungling and blundering. We do not esteem the facts we have as all there are. We prize our advances the more for their promise of something better, we find in them prophecy of yet more splendid development and yet greater discoveries in our science; of more originality and greater simplicity of method. Our country has given us great names to place beside those on the other side of the ocean. Yet we need to greatly multiply the reasons for our boasting.

Personally we hope to avoid pretension, to give out only those lessons our experiences have taught us. My deductions will not be theoretical, but those drawn from actual experience. The importance of adopting simple and direct methods, those tried, tested and practiced by a number of successful operators, should influence all beginners in the choice of methods. The fact that A and B have been the most successful operators, that their mortality has been low, that they complete their work at any cost, that serious post-operative complications have been of rare occurrence are facts worthy of serious consideration by the practically inexperienced. We have a valuable surgical literature recording for us the methods which have withstood successfully many tests in the experience of our best surgeons. By careful study of this literature, which is at easy command, there can be gleaned many lessons that will serve a good purpose in puzzling and trying cases, such as come to every surgeon no matter what his skill.

Though we have been rapidly simplifying our somewhat ambiguous surgical nomenclature there is still much confusion, lack of definiteness of application in many of our terms. In discussing post-operative sequelæ and some of the causes leading to the same, we will not concern ourselves as to terms used to designate pelvic and abdominal conditions, those having for us no very special clinical value. The endeavor will be to use such terms as will make our meaning clear. We hope we have a better understanding —a clearer conception of our subject— than we have of any dead language, the Latin or the Greek, that you will not need an English, Latin or Greek glossary to get at our meaning and that our facts are such as can be made plain even through limited and imperfect English. In our work the sequelæ of what we do is the one

* Lecture delivered at the Post Graduate Medical School of Chicago.

supreme concern. Notwithstanding the sequel of many procedures have been a fruitful source of skepticism with many, the gynecologist and obstetrician have gone on and through improved skill and technique have brushed away many old objections and obstructions; they have grown in the consciousness of their ability to deal successfully with cases which in a near past were allowed to suffer on without relief. We have arrived at the point of knowing that many women suffer from diseases that cannot be cured or even relieved of their severer symptoms by purely medical treatment; that we frequently meet with pathological conditions that medicine, massage, or electricity will not relieve; that grow from bad to worse and that only surgery can reach; that for many cases there are only two avenues of relief, skillful surgery or death.

Here I would mention that a great number of deaths are of patients where there has not been even a suggestion that surgical interference would save life. In many instances death comes before the physician even recognizes the character or gravity of the trouble; before a correct diagnosis is made, and again to that group classed by operators as hopeless when first seen, who are permitted to suffer on and die without an attempt being made or offered for rational surgical relief. Again a third group, a most distressing class to the surgeon, who is willing to give the one chance, those who die on the table, or soon after the operation —never reacting. There is current among the more or less intelligent laity and the more or less, usually the latter, intelligent non-specialist and general practitioners, that the results in abdominal and pelvic surgery are either eminently successful or else woefully responsible for a train of after results in the unfortunately surviving patient, that render it scarcely a permissible branch of surgery unless the former results can be absolutely promised. Just why this should be is a little difficult of explanation unless the early history of this special line of work is considered, together with the methods of certain operators, with whom promises were a part of the means by which operation in many cases was obtained. In no other division, of either medicine or surgery, is it demanded of the physician that his results be absolutely certain and that he guarantee after immunity from all trouble allied to that which he undertakes to remove. Unfortunately there are some at present, possibly not so many as formerly, who in order to obtain chance for operation, were ready to promise everything, just as the ready witted politician has offices waiting for every one whose franchise shall be cast for him. Mrs. X, shall have no more pain, while Mrs. Z, shall be absolutely relieved of every appearance of her monthly disturbance, while Mrs. Q, shall never again suffer constipation or tenesmus, and so on throughout the whole catalogue of diseases, for which operation is ever done or suggested. Now this was all unfair both to patient and operator. Operation is done to definitely remove certain diseased conditions, and to remedy aberrant physiological conditions incident thereto. Any more than this cannot be promised. No more than is promised in the treatment of every other disease. The physician called on to treat a case of typhoid, does not insure his patient in the event of his recovery total immunity from all the sequelæ incident there to. Neither does he on taking charge of the case give absolute assurance of the recovery itself. Neither should the surgeon be required to do so except within the limits of his own experience in the conditions for which he is about to operate. No surgeon should promise recovery to his patients on the grounds of the results of others, unless his own experience is absolutely parallel with theirs. The beginner in abdominal and pelvic surgery, unless after a long and careful preliminary training, and unless accompanied in his work by a careful and experienced operator, must usually have less perfect results than the surgeon of a wide and intelligent experience. I say intelligent experience, because there are operators and operators, and some with a wide and varied experience must never be looked to surpass the line of medocrity. An operator who in the midst of a serious case, looks about him, and addresses the spectators, "Now gentlemen if you have any suggestions to make, I am ready to receive them" is hardly the man any one of you would select to operate upon wife or mother.

A general must be quickwitted, ready to modify the details of his movements to meet strategy of the enemy, but he must needs use his own wits, and not delay to send home for advice. Now all this you

may say is foreign to the subject at hand, but I beg to submit, that, post-operative complications and sequelæ, have to do with all the factors casually suggested in these prefatory remarks. For your more intelligent appreciation of the same I shall divide them, group them, if you please, as I have most frequently met them, into three classes:

First: Post-operative sequelæ due to complications induced by delay in operating.

Second: Complications induced by faulty work and methods.

Third: Sequelæ, which may be said to follow naturally any serious surgical procedure of the nature under consideration.

Incidentally, as following along the line of thought here suggested, will be considered the ways and means best adapted in the light of surgical experience to avoid the avoidable in the way of unsatisfactory results in this branch of surgery.

Delay in operating is at once the bane and danger of all pelvic and abdominal surgery; baneful to the surgeon, dangerous to the patient. This is true in all the various conditions met in the pelvis and abdomen, but especially true in two diverse conditions, pus in the pelvis and in tumors of the uterus. I have long earnestly advocated the prompt removal of all puriform degenerations in the pelvis, and the longer and farther my experience grows, I find I have no reason to change. The logic that hesitates at an early amputation in order to save an inch or an ell of a leg, while thereby life may be risked, is only half-way foolish as compared with the procrastination that dawddles with puriform disease involving the integrity of the vital abdominal viscera. Pus within the pelvis is at once a present and a far reaching menace to the safety of the patient. Its extension is not limited geographically nor anatomically nor functionally. Pus that starts in the tube may burrow through the diaphragm, or show itself in a pulmonary abscess, while, an appendicitis may rush through like a Johnstown flood and assail the very vitals of the economy. Now while the results of retained and imprisoned pus may be thus fulminant in their nature, they may also be insidious, slowly attacking the vitality of the sufferer, bringing on a train of evils, which like gossip growing with a thousand tongues, gains by going and is dangerous apace. Pus if it is not absorbed is irritating and excites inflammation, and inflammation brings about adhesions among the organs surrounding the pus focus. So it is that an inflammation starting in one organ often necessitates surgical interference with another entirely distinct from it physiologically and distinct from it anatomatically. Bowel adhesions are most common in delayed tubal operations, and where the puriform degeneration has gone beyond a certain time the bowel instead of being adherent is often really gangrenous, and its treatment brings into the field the most delicate and painstaking intestinal surgery. Now in these cases we must look upon the intestinal surgery both in the light of operative complication and of being indirectly the cause of post-operative complications and sequelæ. Its presence as a complication of the original operation for the removal of the pus tube is incident to delay in the original operation, and is a necessity on account of this delay. Without it the operation as at present necessitated, would be a failure or a very bleak success. But if on account of this necessary bowel surgery there is after trouble brought on by stenosis and diminished calibre of the gut, is the surgeon or abdominal surgery responsible for such result however unfortunate it may be? Can such sequelæ be for an instant considered argument against either the results or legitimacy of abdominal work, or against the perfection of its methods, apart from preceding calamitous neglect? I think the good judgment of all must decide that in such cases surgery has not had its chance. And so, if after a case has been neglected until a general peritonitis supervenes after a long period of pus-infection, and consequent loss of vitality in all structure, so that, as often happens, the stitches in the abdominal wall will scarcely hold and there is a consequent necessity for the whole incision to heal by granulation, can it be charged to surgery that its methods have been faulty or inefficient? Certainly not. Whatever after complications arise, adhesions, hernia, fistulæ or else of this uncanny clan, must be laid directly at the door of the bad logic and poor wisdom of those to whom the delay is attributable.

The same reasoning, and possibly with even a greater scope in the possibility of the complications, will apply to neglected cases of uterine tumor. These are apt, as you all know, to be tampered with by every agency under the sun. Each and every dilly-dallier is busy seeking methods and modifications and refinements of dilettante-quixotism in order the more to steer shy of the true surgical treatment of which they have a mere smattering of information and this theoretical—not practical. While these empirical devices are being put into practice the disease travels on apace, the tumor increases and trespasses upon other important organs, interferes with their integrity by pressure, contracts adhesions with bladder, intestines and omentum, and, so the disease steadily progresses, the tumor increasing in size and irregularity, which with the increased density and thickness of the adhesions makes its removal a daily increasing difficulty. This is the more likely to be true if tampered with by electricity, with or without puncture—all the more if puncture is used at all.

It will be understood at a glance that the reasoning that applies to the two distinct affections here alluded to, must surgically apply to all diseases of the pelvis and abdomen. This is probably true of appendicitis, than which there is not a more neglected disease, nor one in which so much is "trusted to nature." Delay here is the very essence of danger, and often puts us once and for all outside the possible chance of relieving a patient. It is unnecessary for me to further insist upon this fact here. Both your instructors and your instruction are *en courant* with all that is best on the subject. Under this head it is only necessary to again insist that whatever is logic in one set of abdominal diseases, from a surgical standpoint, is logic in all, and that early surgery soundly applied, is the *open sesame* to all success in their treatment.

The second series of complications I have classed as those due to faulty work or methods. Under this head I have most frequently found adhesions about the incision or indeed throughout the abdomen and pelvis, due to the presence of irrigating fluids. It used to be thought that chemicals were the highway to cleanliness, that an otherwise dirty surgeon could be clean if he had a basinfull of bichloride solution at his side—a sort of dirt "Taboo," so to speak. This had its effect in the complications under notice, and the banishment of this harmful superfluity has worked good in many ways, first by taking away a frequent cause for re-operation, and second, in teaching operators that cleanliness is an essential, inherent trait of the man and cannot be grafted on him by chemicals.

While considering adhesions, it may be well to refer to their imperfect handling as a very pregnant cause of unsatisfactory results in pelvic surgery. When they exist they are not to be attacked wildly and rudely, but are to be broken up carefully, and each step guarded by careful inspection. If by chance the gut is torn through, it is at once to be mended, all else being for the time suspended unless it is the stoppage of hemorrhage. Tears in the omentum are to be dealt with after the same manner, otherwise pitfalls are left for the unwary intestine, whereby to strangulate itself. All peritoneal destruction is to be avoided, and any portion of surface operated upon that can be covered with peritoneum is a direct safeguard against adhesion; this is especially true of large fleshy pedicles. In the removal of diseased organs it is necessary carefully to break up not only the adhesions existing between the parts removed and those remaining, but also those between all remaining parts otherwise healthy. Failure to do this is a fertile cause of bowel obstruction, resulting fatally in cases that would otherwise recover.

Coming next in order as a fertile source of mischief is the faulty handling of hemorrhage. At the bottom of much hemorrhage is the reprehensible use of cat-gut. The use of this agent ought to be avoided; except for the very smallest vessels it is not so safe as silk, and the latter has too much to recommend it, too many successes on its side to be theoretically argued out of sight. The careful tying of every bleeding vessel as it is met, and of pedicles in portions small enough to secure perfect stricture, with sufficient button, to prevent slipping, will give security against hemorrhage as it most freuqently occurs. Just here I will memtion a method or rather a procedure by which all surgery, especially that of hemorrhage, is presumably made easy. I refer to the Trendelenburg position. This was

originally invented for the performance of suprapubic cystotomy. Those of you who have seen this operation know just how much need there is here of the Trendelenburg position, and in my opinion there is but little more use for it anywhere else. In all operations in which hemorrhage is likely to occur by oozing and indirect leakage it is a positive disadvantage. The patient is stood nearly on her head, and the natural gravity of the blood reversed. Now this together with a weakened circulation and the presence of surgical shock, will give apparently a dry field of operation, but when the natural recumbent position is assumed it will at once become prone to oozing and leakage which may soon become a serious matter. All oozing must be controlled and any step which veils or conceals its presence is a menace to the safety of the patient.

In this connection we may profitably consider improper drainage as a cause of serious complication after operation.

Drainage is well recognized as a surgical necessity in operations of all kinds. Under certain conditions its employment is not disputed or questioned, except in the abdominal cavity. Why this is so is not always easy to explain. In fact it is probably best not to attempt to explain every vagary that comet-like flits across the unsettled minds of many following the plough in the furrow of abdominal surgery. It is enough to carefully listen to the arguments on each side, weigh them well, see wherein is contained the least fancy and the most fact and follow the lines of presumptive safety. Much of the dissatisfaction over drainage is the result of crude methods and faulty care of the tube, and indeed of the patient. Most of those now condemning drainage have vacillated between one method and another and finally, without having gotten satisfaction out of any method, they condemn all. Gauze, lampwick, bone tubes, new devices to keep the tube clean, all have failed, and like King Solmon after he had gone the rounds, they cry, "Vanity of vanities, all is vanity." The proper way to apply any method is to study the end to be attained, and then use means to accomplish this end. To remove accidental debris, irritating or accumulating fluids there is nothing that so well answers as the small glass drainage tube reinforced with the long-nozzled syringe. All other device is unnecessary. Gauze is a good primary but a poor secondary drain. It will not discharge lymph, nor will it insure the non-disturbance of the parts on its removal as is afforded by the simple glass tube. It like wise promotes adhesions, and these are the factors necessitating much after-surgery in the abdomen. All foreign matter introduced at the time of operation must come under the head of irritants and this is true of the drainage tube; the more so the longer it remains unless it is absolutely clean, and kept clean or in fact unable to get dirty. The improper handling of the drainage tube, its shifting or its rude handling may make it, in careless or unskillful hands, a source of danger and dis, comfort to the patient. This is, however- no argument against its proper use, and the operator who gets bowel fistulæ from it simply confesses that he has placed it improperly, while he who lays ventral hernia to it as a prime factor forgets that herniæ rarely appear in the lower angle of the wound where the tubes should always be placed.

Under the head of foreign bodies as a cause of mischief it is necessary to class big and unnecessary ligatures. Many small vessels can be secured by torsion whereby tying is rendered unnecessary. When this can be safely done it is by far preferable to the use of multitudes of ligatures. Big, heavy, braided silk is apt to cause trouble by non-absorption and by making a focus for suppuration. Hence it is the rule to avoid ligatures heavy past the absolute necessity of each individual case, and to apply as few as possible.

Big ligatures probably are oftener the cause of abdominal fistulæ than any other factor, unless it be in those of a fecal nature. These latter are caused by failure to mend weakened spots in the gut, or by badly placed drainage tubes.

I have neglected to consider one point in reference to drainage and to do this I shall go back for a little. I mean the consideration of the after condition of the patient. She is always quiet except in the rarest cases; her recovery is non-febrile, her tongue is clean, her secretions normal. I am speaking of course of cases in which there have been pus and adhesions. In simple cases this condition of affairs ought always to obtain. This is in

marked contrast with cases in which, under similar conditions of operation drainage is not used. The contrast is as marked as that laid down in the books between concussion and compression of the brain. The quibblers cry your operation has not been clean or you would not need drainage; and again, before this alarm has died away, another investigating army explain away the use of the tube because it infects the stump and carries millions of microbes into the abdomen. Here is at once a confession and a plea. First, they do not know when or how to use the tube, and second, they explain it away on the ground of its causing what on the first hand they confess is a necessity for its employment. Such argument needs but little attention.

Passing on I shall class as imperfect surgery all that leaves behind removable diseased organs or conditions. Under this head must be placed vaginal puncture for pus in the tubes, and the vaginal removal of diseased organs. Both of these operations are unjustifiable: first, because they are incomplete, and second, because they do not allow the operator to manipulate freely enough to entirely relieve the patient either of her danger or discomfort. Pus tubes are not a simple condition, but are complicated with adhesions and, therefore, in order to deal with these all the vantage ground of operative position must be sought. This is impossible in the vaginal operation. Adhesions in pelvic disease are often the bulk of all the trouble, and hence they must not be left. Abscess of the pelvic organs is rarely a simple sac, and, therefore, cannot be cured by mere puncture. That once in a while such a case is met is no argument by which a general method is to be laid down. Enucleation and removal, drainage and freeing adhesions is the only proper mode of procedure.

A word now as to conditions following operation, traceable often to bad care of the patient or to improper surgical procedures. At the head of the list is ventral herniæ. Many patients are directly responsible for their own condition in this respect. Too early rising, too early laying aside the bandage, and foolish physical exertion, such as dancing, riding and the like, frequently bring on the condition for which the surgeon is in no way responsible. But on the other hand, over-anxiety of the surgeon to get an empty bed in his hospital or to chronicle a wonderful recovery, are among these secondary, non-surgical causes of this accident. The incision and its closure are to be carefully considered in this accident. A short incision, with the stitches uniformly introduced on either side so as to preclude turning in of the skin edges is this the best safeguard against accident. Personally I do not agree with those who introduce layer after layer of sutures. Again it is a recognized fact that incision through one of the recti, is less apt to cause hernia than linear incision. I submit that a series of carefully watched operations on this line would be of the greatest interest.

I have now gone over some of the chief causes of accident and complication in abdominal work, enough at least to give you food for thought, in the lines of real experiences without any theory whatever, and it remains for me at this time only to refer briefly to some of the after conditions of operation for this set of diseases, which naturally are to be expected. First are the phenomena attending the removal of the appendages. All women are not affected alike. Some endure their removal with immunity from discomfort, while others are for a long time annoyed with the phenomena attending the menopause. Hence it is not safe at once to promise perfect comfort to these patients, nor indeed to tell them even that the menopause will infallibly at once ensue. Some women persist in periodic hemorrhages, some cease at once, others continue more regularly than ever. The why of all this is not clear. Again in chronic cases, where the pain and discomfort has lasted long the recovery is often more or less tedious. Pain has become engrafted upon the organism and time only will remove it. To such patients must be given encouragement to await patiently the gradual restoration to health, just as they would expect to do in the external surgery of the body. Miracles are not to be expected here, neither is it fair to promise them. The same careful consideration of all the probabilities of the case should here be made; the same honest expectation of life and health afforded; no more, no less.

The manner, matter and methods of

abdominal surgery have to deal with humanity in channels that most concern it, and hence they afford scope for the widest humanitarianism, the truest philanthropy, the bravest hearts.

Our profession is adjusting itself to the spirit of the period; to its spirit of enterprise, research and invention. We now come to Chicago as to the world's great school, to this great city of the great West, which, in little more than half a century has become the second city of our country in population, and *very strongly second* in commercial importance; the enterprise of whose people could not be burnt out with the burning over of more than two thousand acres of the city's area. And here within its corporate borders has been built as by magic the "White City," in fitting celebration of the event that gave to mankind a new world. And thick peopled is this "White City," with those from our many states and from over the seas, all moving bewildered about what is so vast in suggestion, so immense with what has been done, is doing and is promised. Its walls of themselves make all the world marvel at the creations of American genius and enterprise. Amid these creations we stand amazed by the beautiful designing of the architect, by the studied, skilled, cunning work of the mechanic; by that beauty, proportion and strength which has been evolved from rude and uncouth conditions, all illustrative of the manual dexterity, the strength, skill and wisdom of master workmen. As we note the achievements of mechanical and industrial art we feel the stronger assurance of the immense possibilities of our own art,—we do not look for results to peculiar inspiration but to hard work. Our aim should be to make our art the supreme one, as it is *the one* that most intimately concerns human physical well being, the need to be workmen, trained to surgical dexterity, to greater certainty and accuracy than that which directs the thought and hand of the sculptor.

# CLINICAL LECTURES.

## PES PLANUS; CYST OF THYROID; MULTIPLE URIC ACID CALCULI; SARCOMA OF JAW WITH SUSPECTED SYPHILIS.

ROSWELL PARK, A. M., M. D., Buffalo, N. Y.

Six weeks ago I operated on this boy for painful flat-foot, chiseling off the head of the astragalus on each side, so as to allow the feet to become slightly inverted and arched. If you will notice the impressions of bare feet you will see that we naturally walk on the outer side of the foot. This boy, on the other hand, was walking with everted feet, bearing his weight on the inner portion of the soles. After the operation the feet were dressed antiseptically and encased in plaster-of-Paris, which remained on five weeks. The patient is about to leave the hospital, the wounds are entirely healed and the shape of the feet is all that can be desired. It will be a month or six weeks longer before the tissues will have become firm enough to permit the child to walk. If, even at the end of that time, there is any tendency to stretch and allow the foot to regain its malposition, it will be necessary to apply a metal brace, suitably moulded to the lower surface of the foot, and then bending at a right angle and reaching up the side of the leg.

The first operative case is that of a girl of seventeen, with a tumor in the middle of the neck, which is probably a small goitre. In reply to questions which were not leading, she tells me that the tumor was first noticed at the time of puberty, there being at that time a small enlargement in the middle of the thyroid body. At each menstrual period, it has grown a little, receding somewhat before the next period but gradually becoming larger. This history is an illustration of the mysterious sympathy existing between the thyroid and the sexual organs of the female, a sympathy that is manifested in

the growth of the thyroid during pregnancy. In some ill-understood way, the thyroid has something to do with the elaboration of the blood corpuscles, and when we remember that during pregnancy and at the menstrual periods there are calls for the renewal of the blood and an increase in its elements, we may understand somewhat the connection between the enlargement of the thyroid and the state of the sexual organs. Sometimes after delivery the enlargement of the thyroid retrogrades; sometimes it does not. I have now under care two private patients who have had three children, and each pregnancy has caused an enlargement of the thyroid, both lobes being enlarged, though not symmetrically. In the present instance, it is the central portion of the thyroid body—I do not like to call it a *gland*—which seems to be enlarged. The girl came to me a little while ago asking what could be done, and I told her there were three ways in which the trouble could be treated: first, by applying or administering drugs, a method which would do little or no good; second, by the use of electricity, which sometimes helps the condition a little but which is always slow and often futile; third, by surgical interference which is immediate and radical in its relief. Although I said nothing to her to urge operation, she at once jumped at the chance and decided to have the mass removed. If the tumor involved the whole thyroid, I should be averse to operating, for it is known that the complete extirpation of the thyroid is sometimes followed by a peculiar vital depression and imbecility to which the name cachexia strumipriva has been applied. But we have learned by experiments that a portion of the thyroid, even four-fifths, may be removed without danger, the remaining structure being sufficient to perform the function of the whole body.

This tumor is probably cystic.

[The tumor was exposed by a median line incision and found to be pedunculated. It was ligated with cat-gut and cut off from the small pedicle; the external suture was of the subcutaneous, continuous kind, in order to avoid cross-marks in the scar. The bandage over the antiseptic dressing was extended below the axillae in order to prevent disarrangement.]

---

The next patient is a decrepit old man, somewhat emaciated, who has suffered for at least two years with such bladder symptoms as frequent micturition, with direct and referred pains. He has been compelled to give up his occupation and, as he feels better in the recumbent posture, to spend most of his time on the lounge. His symptoms point either to enlarged prostate or to a calculus, or both, with consequent irritability of the bladder. He has been sent here from quite a distance, one of his attending physicians having touched a stone with a sound. On my first examination with ordinary manipulations I failed to discover a stone, and even the assistance of the finger in the rectum did not avail. I then drew off the urine and filled his bladder with a boric acid solution till he complained of distention, and then passing the sound I touched the stone. A difficulty in introducing the sound and the rectal examination showed also that there was an enlarged prostate, and, through the patient had just emptied the bladder as he supposed, nearly half a pint of residual urine was drawn off by the catheter, having been retained on account of the prostatic enlargement. I want to impress on you the fact that a stone which eludes ordinary searching may be detected by first distending the bladder.

Two questions arise, what is the character of the stone, and what is the best means of removing it? The urine is acid now and although the nucleus of the stone may be phosphatic, the shell at least is probably composed of uric acid. Uric acid calculi are always hard and difficult to crush, and an attempt to remove the stone in fragments through the urethra would be prolonged to a hazardous degree. I found also at my examination that the end of the sound caught in one or two places in the interior of the bladder, showing that there are pockets in which some of the fragments of the stone might lodge and form nuclei for other calculi. We must have recourse then to a cutting operation, and I have decided to enter the bladder by the supra-pubic route, which is not the quickest but which gives the best opportunity for exploration. The perineal section to a man used to the manœuvre is a rapid and may be made a brilliant operation, but it may be difficult to find the stone afterward. The supra-pubic section takes a few minutes while the

perineal requires only a few seconds, but by choosing the former, I run no risk of injuring the prostrate, and I can find the calculus more readily and extract it entire. The supra-pubic method or *sectio alta*, was in vogue many centuries ago, but was abandoned for the perineal operation and has been revived only during the present generation. By many surgeons it is now used almost to the exculsion of the perineal operation. I do not believe however, that any one method is of intrinsic superiority, and think that each particular case should be studied and the decision made as to the preferable method in accordance with its special features.

The shaving of the field of operation has been deferred till anæsthesia is complete, in order not to alarm the patient who is quite timid. The urine is now withdrawn and the bladder filled with a boric acid solution. The attempt to pass a regular stone searcher with an abrupt curve, meets with considerable difficulty, but this large steel sound passes easily and you can hear the click of the instrument against the stone, which seems to be a large one. With the bladder distended, the peritoneal covering is raised some distance above the pubis, so that it is easy to enter the bladder without penetrating into the peritoneal cavity. The longitudinal incision in this instance, fails to encounter a plexus of veins which is often found in the prevesical space, and the hemorrhage is not annoying. The handle of the sound is now depressed so as to present the other end as a guide for the incision into the bladder, but before the knife is used I will pass two heavy cat-gut sutures through the bladder wall and hold their ends with hæmostats till we need to tie them. It would be more difficult to get the threads in a position with the bladder empty and collapsed. A considerable gush of fluid follows the penetration of the knife, and on inserting my fingers I find four calculi, which you see are hard and have the characteristic appearance of uric acid. The prostate is so much enlarged as almost to tempt me to remove a part of it, but the patient is old and feeble, and I do not feel justified in adding to the necessary shock of operation. Behind the prostate is a pocket in which residual urine has remained and caused so much discomfort and in it I find a fifth calculus.

After thus cleaning out and washing the bladder with boric solution, I sew the margins of the wound up to those of the skin wound with a single suture on each side, preferring this to closing the incision, partly from a desire for the increased security of this method, and partly because his bladder needs now rest and free drainage, both of which can be thus better secured. A double catheter is passed into the viscus so far that its lower end projects down to the pocket behind the prostate; it is held in this position by a silk suture passed through the skin. Iodoform gauze is placed around it and in the wound. A large mat of dressing, perforated for the passage of the tube, is applied over the lower part of the belly, held in place by adhesive strips and a double spica bandage, and the patient put in bed.

[He made a rapid recovery].

---

The next case is rather obscure, and I am unable to tell you in advance either its exact nature or the method of operation that will be followed. The patient is a man about fifty, who presents enlargements under and apparently attached to the lower jaw bone. On one side the mass is rather soft and small, on the other it is hard and nodular and considerably larger. It is eight months since the trouble was first noticed and in that time the masses have grown so as to interfere with breathing and swallowing, though they are not very prominent externally. The patient has given to one member of the staff an account of syphilis, and has denied all venereal history in his statements to another. It was decided to give him for a time the benefit of the doubt and to treat him upon a tentative diagnosis of syphilis. It must be borne in mind, however, that the venereal history is contradictory and the objective evidences not conclusive. Moreover, the mass has continued to grow in spite of anti-syphilitic treatment and the location is an unusual one for the syphilitic gumma. We must also consider the possibility of the growth being sarcomatous and, for the sake of completeness, we might think of actinomycosis. Such a case is rarely seen in the human being but the patient is a common laborer and he might have been exposed to the fungus. Acting on the supposition that the tumor is a gumma,

breaking down in the interior, I have made preparations to open and curette it and to cauterize the walls of the cavity. In this way the patient would be relieved of actual pressure symptoms and with general treatment would probably recover so that the immediate removal of the entire mass would be unnecessary.

The case is at least a lesson to you that an exact diagnosis before the removal and examination of a growth is often extremely difficult, if not sometimes impossible. But I want you to learn an even more important lesson, namely, that in some instances an operator can not tell beforehand just how he will proceed and each step in the operation may depend upon some unexpected development,so that the prudent surgeon must be prepared for emergencies as well as for an anticipated line of action. You see among other instruments in the tray bone-forceps and the chain saw, so that if we have to deal with a malignant growth affecting the maxilla, the operation may not be delayed. These instruments, however, will probably not be needed.

Partly for diagnostic purposes I shall attack the smaller and softer mass first. On opening into it I find that its interior seems to have undergone cystic rather than suppurative degeneration, and this fact throws doubt on the diagnosis of specific trouble. Before attempting to dispose of this growth, I will open into the larger tumor to see if both are of the same nature. This tumor cuts, not like a gumma, but like cartilage and, in spite of its size, I find no breaking down in its center, whereas a gumma of this size would be almost certain to contain a cavity. We must abandon the diagnosis of syphilitic gumma and proceed to eradicate a sarcomatous mass which involves the lower jaw. The precaution of having in readiness the bone-saw and forceps was a wise one, for I shall have to remove a portion of the maxilla between the angle and the symphysis, at least on the side of the larger growth.

[Operation proceeded without difficulty, and the patient's condition was for the time being very much improved. But later a very slow recurrence with infiltration was observed, and further operation was deemed inadvisable. He went to an adjoining alms-house and finally disappeared from observation.]

# COMMUNICATIONS.

## THE EYE-SYMPTOMS OF BRAIN DISEASE.

CHARLES ZIMMERMANN, M. D.,* Milwaukee, Wisconsin.

In the last few years quite a number of cases have come under my observation in which the examination of the eyes, especially with the ophthalmoscope, revealed pathological changes of the visual organ which gave the first hints of an affection of the central nervous system and proved of great value in determining the diagnosis of a brain disease. They thus belong to a department of medicine in which the fields of the general practitioner and of the oculist border on each other, and in which both ought to be interested alike.

The reason for the frequent association of ocular affections with those of the brain will at once become apparent if we remember what a very large extent of the latter is placed in relation to the eye. This may advantageously be looked at from four different points of view: *first*, the developmental; *secondly*, the anatomical relation, inasmuch as the optic fibres from the optic foramen to the visual centre are situated within the cranial cavity; *thirdly*, the connection by the ocular, the 'fifth,' the facial and sympathetic nerves; and, *fourthly*, the common causes for associated diseases of both organs.

Consider the eye developmentally, and the retina and optic nerve are to be regarded as a prolongation of the brain. In a very early period of foetal life, when the anterior portion of the medulary tube

*Ophthalmic and Aural Surgeon to St. Mary's and Emergency Hospitals.

has been transformed into the three cerebral vesicles, from the foremost of these a new vesicle, the primary ocular, grows out, remaining connected with it by a hollow tube—the first trace of the optic nerve. From the cell-layer covering its pole the lens develops, pushing its wall inwards, so that the hollow sphere is converted into a shell consisting of two layers —the secondary ocular vesicle. Its inner sheath becomes later on the retina and its outer layer the pigment epithelium. In this way the retina and optic nerve are advanced or external parts of the brain. Therefore it seems quite natural that pathological changes in the intracranial portions of the brain, that is in the brain proper, may be propagated to the external parts, that is retina and optic nerve, and that these may show alterations indicating associated or analogous affections of the encephalic parts. The three sheaths of the optic nerve are a direct continuation of the three meninges, the dura mater, arachnoid and pia mater, separated by the subdural and subarachnoidal spaces, which communicate with the identical cerebral spaces. The subdural space of the optic nerve forms in the normal eye only a very narrow fissure, whereas the larger subarachnoidal represents the so called intervaginal space. The spaces are lined with endothelium and are to be considered as lymph-channels of the eye. Schwalbe, Quincke, Deutschmann and Gifford demonstrated that in these spaces there is a lymph current from the brain to the eye.

We must be familar with these facts in discussing one of the most important ophthalmoscopic symptoms in brain diseases, the optic neuritis usually called choked disc or papillitis. In this disease the optic disc presents the aspect of congestion with œdema, increased redness, blurred edges, radiating striation of whitish nerve fibres spreading into the retina, and sometimes small hemorrhages with general cloudiness. The arteries are concealed at their emergence and narrowed. The veins are dilated, are tortuous, look dark and as if cut into pieces. The swelling of the disc, which in some cases may become so intense that it forms a fungi-form tumor, its sides overhanging the retina, is recognized by the relative displacement of different parts by parallactic movements of the lens, and, in the direct method of ophthalmoscopical examination, by its changed focus in comparison to the retina amounting sometimes to four diopteries. The adjacent portion of the retina may take part in the inflammation and present areas of opacity and hemorrhages. If it extends to the macula, the familiar stellate form of white streaks and dots, as seen in renal disease, appears, caused by a degeneration of the radiating fibres of the fovea centralis.

The *pathological anatomy* of papillitis consists of a swelling of the disc, visible even to the naked eye, rising from two to three millimetres above the level of the choroid. It is caused by dilatation of the blood vessels, œdema, proliferation of nuclei, emigration of leucocytes and hypertrophy of nerve fibres. The nuclei may form a thick layer around the blood vessels and the nerve fibres. The coats of the blood vessels are thickened by nucleated tissue, the nerve fibres show varicose enlargements from an accumulation of fatty globules which are the products of a degeneration of myelin. Sometimes colloid corpuscles are found between them. The nuclear layers of the retina are thickened and the fibres of Müller hypertrophied. The trunk of the optic nerve shows changes of an inflammatory character, sometimes as far back as the chiasm, increase of nuclei, distension of vessels and thickening of its trabeculæ. The sheath is mostly distended, reaching sometimes such a considerable degree that it forms an ampulla close behind the globe. The development of papillitis may take place, in the cases of rapid course, in two to three weeks, remain at its acme two weeks and then subside. This happens mostly when depending upon a cerebral affection of transient, and especially of syphilitic character.

But in other cases optic neuritis may be very chronic; for instance, when caused by a cerebral tumor which progresses very slowly. Then it may last for weeks and months, and then subside and pass into atrophy. The papillitic atrophy is brought about by the shrinking and strangulating influence of the connective tissue into which the newly-formed inflammatory products have been transformed. By its contraction the vessels become narrowed and may be partly concealed. The disc itself assumes a greyish tint, the lamina cribrosa remaining

perfectly veiled. Its edge is blurred, although in some cases it may become so sharply defined that it is very difficult to trace the atrophy to its origin.

One of the strangest peculiarities in some cases of papillitis of much marked pathological change, is the integrity of sight, visual field and color perception. In others it is impaired or lost. Pain in the eye is very rare, and if in the head, is due to intracranial affection. The impairment of sight comes on rapidly or slowly, never suddenly. Vision may fail in the course of a few days. The field of vision is affected in various ways. The mechanism by which sight is impaired is very important, especially in regard to the prognosis. In intracranial disease the loss of sight may be caused by the intraocular changes of the papillitis or by an affection of the visual fibres or centres. A sudden blindness in optic neuritis comes on only when associated with mischief farther back in the optic path. The amblyopia caused by the inflammatory process during its acme may nearly disappear as the inflammation subsides, but again be renewed by the subsequent contraction of the connective tissue.

Even after the papillitis is healed with restoration of vision, this may be lost entirely from an affection of the optic fibres within the cranium and without fresh ophthalmoscopic changes. Thus the discrepancy between the affection of sight and the course of papillitis indicates retro-ocular affections. Intracranial diseases are the most common causes,—tumor, meningitis, abscess, hydatid disease and softening of the brain.

Cerebral tumor ranks highest in the etiology of papillitis, which is *the* ocular lesion characteristic of it. According to Gowers, neuritis occurs in about four-fifths of the cases of tumor. Annuske and Reich collected 88 cases with ophthalmoscopic examination and autopsy, and found that in only five per cent. there was no ophthalmoscopic change.

Glioma, sarcoma, tubercle and syphiloma are usually associated with optic neuritis. But this has no peculiar features enabling us to make a diagnosis in regard to the nature, position or size of the tumor, since it was found to be absent in some cases of glioma, which invaded the brain substance only, not increasing its bulk.

The mechanism by which optic neuritis is induced by encephalic disease has been explained by various theories. Von Græfe assumed that the increased intracranial pressure caused an impediment to the return of blood from the eye to the cavernous sinus, thus leading to hyperæmia and dilatation of the central retinal vein. This, however, did not explain the origin of inflammation. In addition, its presumption was not anatomically correct, in that the cavernous sinus is assumed to be the only outlet for the central retinal vein. Sesemann (in 1869) demonstrated that this opens either into the superior ophthalmic vein or directly into the sinus after anastomosing with the superior ophthalmic by large branches. The superior ophthalmic communicates partly with the sinus, but empties by far the greatest portion of its blood through the angular into the anterior facial vein, which will at once relieve the affect of intracranial pressure upon the cavernous sinus.

Manz and Schmidt called attention to the frequently observed distension of the optic sheaths in papillitis, caused by cerebro-spinal fluid forced into the subvaginal space by the intracranial pressure, which might produce papillitis by the compression of the optic nerve and its vessels. In many post-mortem examinations of cases of choked disc however, this distension, or hydrops of the sheaths, was not found at all. Leber, and later Scimemi, attributed to the pathogenic material in this fluid the exciting cause of neuritis. Deutschmann (1887), by recent experimental investigations, came to results in favor of Leber's opinion. He injected agar-agar, stained with india-ink, into the subvaginal space of the rabbits eye, either directly or through the subdural space of the brain. When he proceeded aseptically, he found no choked disc even in those cases in which, after forced injections, the post-mortem examination showed a layer of black agar-agar, one-half to one millimeter thick, covering the whole surface of the brain and so completely filling the subvaginal space that the ophthalmoscope revealed a black ring around the disc. If he injected agar-agar with an infusion of staphylococci into the optic sheath, or tuberculous pus into the cranial cavity, the typical picture of choked disc was obtained. In all these cases inflammatory changes of the papilla

existed ; never compression of the vessels. He thus comes to the conclusion that, in man, mere increase of pressure does not cause choked disc. This follows only when pathogenic matter, of either chemical or parasitic nature, enters the optic sheath in the cerebro-spinal fluid. In cerebral tumor, the pathogenic material is produced by the metabolism in the tumor. The increase of the intracranial pressure comes only so far into consideration as it favors the entrance of the pathogenic material into the optic vagina. Zellweger (1887) came to the same experimental results with injections of sterilized emulsion of cinnabar. Furstner (1889), from pathological examination, infers that, by changes in the optic sheaths and by the perineuritis which he found, impediments arise to the lymph circulation, especially its outflow, which entail a process of swelling and proliferation and later on destruction of the nervous substance. Benedict ascribed it to the vaso-motor nerves. Hughlings Jackson and Galezowski consider the decending optic neuritis as a propagation of the inflammation of the brain.

From all these observations it seems to be most probable that the papillitis dependent upon intracranial diseases originates in a descending inflammation of the optic nerve, the evidence of which may be traced in the nerve itself and in its sheath, conveyed from diseased portions of the brain into the subvaginal spaces by a powerful lymph-current. The pathogenic material will accumulate mostly at the cul-de-sac of the space next to the globe and therefore produce the most striking changes at the intra-ocular end.

Purulent irido-choroiditis gives another example of the rapid transportation of purulent matter from the cranial cavity through the optic sheaths into the perichoroidal space by means of the lymph-current. The mechanical congestion in choked disc is due to a compression of the vessels by inflammatory products in the substance of the papilla. The intracranial pressure, as well as the distension of the sheath, alone do not cause but may intensify the process. Direct pressure on the optic fibres in the chiasm, at the optic foramen or at the base of the brain, by tumors, internal hydrocephalus, distended third ventricle, meningeal exudations, aneurisms or exostoses of the cranial bones may cause simple atrophy of the optic nerve without preceding papillitis. Blindness, however, may occur in diseases of the brain even without ophthalmoscopic changes.

This brings us to the second point of relation of the eye to the brain—namely, the *anatomical*. In order to get an exact idea of the range of the visual nervous system we have to trace it from its peripheral termination and follow it to its nuclei and centres in the cortex of the brain. It will be readily conceived that we cannot do this anatomically or histologically. It is only possible by a combination of the conclusions obtained by anatomical, pathological, clinical, physiological and experimental researches. The peripheral termini of the visual organ—the cones and rods of the retina—which are excited by their adequate stimulus, the light, are connected with nerve fibres without medullary sheaths, being simple axis-cylinders spreading in the innermost layer of the retina. They all converge in the optic disc where they assume neuroglia and form the trunk of the nerve. In the orbit this, about thirty millimetres long, runs to the optic foramen and meets its partner of the other side in the chiasm.

In regard to the position of the fibres in the optic nerve supplying the different portions of the retina, a case published by Schmidt-Rimpler (*Arch. of Ophth.*, xix., p. 133) gives us valuable information: A man received, from a blow with a spade, a comminuted fracture of the posterior portion of the right parietal bone, a few centimetres below the sagittal suture. Left-sided hemianopia of the right eye resulted. The post-mortem examination revealed constriction of the upper part of the right occipital lobe. The secondary degeneration showed the following distribution of the fibres in the optic nerve: "In the vicinity of the eye, the fibres supplying the macula lie in a wedge-shaped bundle on the temporal side of the nerve; the fibres of the temporal portion on the upper and lower periphery, encroaching somewhat upon the temporal as well as the nasal side; the fibres of the nasal portion in a part embracing the centre of the optic nerve and the middle third of the nasal half of the periphery. In the neighborhood of the optic foramen, the fibres which supply the temporal portion of the retina occupy the lower periphery of the nerve, a

larger portion of the nasal and a small, lower one of the temporal periphery; those supplying the nasal portion of the retina occupy especially the upper periphery; whilst the macular fibres are found more in the centre." The assertion of Siemerling that the uncrossed fibres should lie on the lateral side of the nerve seems not proven; nevertheless individual differences are possible.

This way of tracing the visual fibres, granted in this case by nature, was anticipated and experimentally cultivated by Von Gudden as a special method of investigation—the degeneration method or so-called atrophy experiments—and it is due to this mode of research that we owe our chief knowledge of the arrangement of the optic fibres in the chiasm, and of their further course in the brain. His experiments on animals proved a semi-decussation of the fibres in the chiasm in the rabbit, cat and dog, and his studies of horizontal sections of the human chiasm resulted in his observation that the fibres which cross lie mostly in the lower half of the chiasm and those which do not cross in the upper half.

Michel is perhaps the only author who insists on the total crossing in the chiasm in the higher mammals. But his observations are conclusively refuted by the experiments of Singer and Munzer, and, very recently, of Darkschewitsch (*v. Graefe's Arch.*, 37, 1891). Bernheimer (*Arch. of Ophth.*, xx. 1891), following the course of the optic fibres by means of the development of their medullary sheath in thin serial sections of the human chiasm, proved that there are fibres in the upper half of the human chiasm which pass directly from one tract to the nerve of the same side, and that the number of the crossed fibres is considerably greater than the number of the direct ones. From these and other observations we are justified in taking for granted that the fibres of the chiasm intricately interlace, and cross one another so that, of the optic nerve, about three-fifths—representing the fibres from the nasal side of the retina—pass into the opposite tract, and two-fifths—from the temporal half of the retina—enter into the tract of the same side.

According to Siemerling, the uncrossed bundle lies in the centre of the tract and never reaches the periphery. Delbrueck (*Arch. f. Psych.* vol. xxi 1890) says: "In the tract the rule seems to be that the direct fibres are mingled with those that cross." Both tracts diverge backwards and form a rhombus with the cerebral peduncles, pass under these and over the gyrus hippocampi and divide into roots. The lateral root goes to the corpus geniculatum laterale; to the thalamus opticus, especially its posterior portion the pulvinar, and to the anterior corpora quadrigemina. In the latter, commissures of optical fibres of both sides are observed, which Charcot took for the complemental decussation of the fibres not yet crossed; but this theory is unproved. These ganglia are the primary optical centres from which the radiating visual fibres of Gratiolet spread into the white substance and the grey cortex of the occiptial lobe.

The occipital lobe is considered to be the centre of vision, although the exact delimitation of the visual sphere has been a matter of controversy in the investigations of many physiologists. Besides, it is now generally agreed that each species varies somewhat in its functional areas, so that we cannot simply apply physiological results in animals in forming an exact localization of the human function, but they are of great help. Munk first showed that unilateral extirpation of the visual sphere, by a section in the parieto-occipital fissure, localized it exclusively in the occipital lobe and produced homonymous hemianopia from paralysis of the corresponding sides of both retinæ. Ferrier (*Croonian Lectures*, 1890) supposes that Munk's operations for removal of the occipital lobe would be the cause of secondary implication of the angular gyrus or its connections. He thinks, from the results of bilateral destruction of the angular gyrus described by himself, Munk and Schæfer, "that the angular gyri are more particularly related to the area of distinct vision and, accordingly with the maculæ luteæ. The pathological facts in man render it necessary to assume that the region of the yellow spot is represented in the angular gyrus of each hemisphere, though more in that of the opposite side." "It is in the higher visual center, where the two half-vision centres are probably blended, so that the former can compensate its fellow of the other side to some extent, whereas the half vision centres cannot supplement each other." (Gowers.)

The partial defects in the visual field seem to be dependent on partial lesions of the optic radiation and not of the cortex. The hypothesis of Munk and Schæfer, that the different portions of the retina are represented in corresponding regions of the occipital lobe, cannot be considered as a fact. Ewens has, under the direction of Ferrier, collected and analyzed the majority of the recorded cases, with necropsies, of hemianopia, depending on cerebral lesions with implication of other regions. Of 41 cases of hemianopia, 15 were from diseases of the occipito-angular region, 2 of the angular and supramarginal gyri only, 15 from disease of the occipital lobe alone. In the other cases the lesions were of a diffused character, the angular gyrus being implicated in all. Seguin and Nothnagel think that the cuneus, and Wilbrand that the apex of the occipital lobe, have a special relation to visual perception. According to Ferrier the visual area of the cortex is not a merely functionally differentiated region capable of replacing or being replaced by other cortical areas, in as much as destruction of the visual centres leads to atrophy in the primary optic centres, optic tracts and nerves ; and conversely, destruction of the optic radiations leads to atrophy strictly confined to the regions included within the visual zone.

The chief *functional disturbance* in lesions of the visual path from the optic centres down to the chiasm, is homonymous or lateral *hemianopia* of the opposite halves of the visual field, which may be complete or incomplete. The line of division is usually sharp and vertical, and the blind sides usually have no sensation of light. Central vision is often preserved corresponding to a slight projection of the line of separation for three to five degrees into the blind side at the region of the macula. But the defective half never encroaches upon the seeing side beyond the point of fixation, so that this would be situated in the blind portion. The explanation of this was the assumption that the macula of each side receives fibres from each tractus. If this be the case, in lateral hemianopia from a disease of one occipital lobe, destruction of the other occipital lobe would produce absolute blindness through bilateral hemianopia. Foerster, however, observed such a case of bilateral hemianopia. (V. *Graefe's Arch.*, vol. 36, No. 1, p. 94), in which the area of central vision was preserved in both halves of the visual field. He thinks it therefore to be more reasonable to attribute the preservation of central vision to a specially favorable arrangement of blood vessels supplying the sphere of distinct vision in the occipital cortex. Even if by thrombosis of the main vessel supplying the occipital lobe, the nutrition of the cortex in a large extent is cut off, the zone of distinct vision, by the numerous anastomoses of its vessels, receives sufficient nutrient material to preserve its function. Schweigger (*Arch. of Ophth.*, 1891, 1, p. 84) confirms Foerster's hypothesis from the observation of a similar case of bilateral hemianopia with preservation of a limited central field of vision, which he supposes to be due to a particular arrangement in the central apparatus. Foerster infers from his case that the cortex of the occipital lobe is the centre for the sense of locality and the topographical ideation and representation, no matter whether acquired by the visual or tactile organs or the perception of muscular movements, or by description.

If homonymous hemianopia shall be of *localizing value* concomitant symptoms are to be looked for. For distinguishing tract and central hemianopia Wilbrand has suggested the following test advocated by Wernicke and Seguin: If the pupil does not react to light thrown on the hemianopic portion of the retina the optic tract is affected, because the pupillary as well as the visual fibres lie in this path, being connected with the oculo-motor centres by the ganglion habenulæ, the posterior commissure and the nucleus of Von Gudden. The pupillary fibres have a thicker calibre than the visual fibres according to Key, Retzius and Von Gudden. Lesion of the cortical centres causes hemianopia with complete hemiplegia, and aphasia is likely to be caused by a softening of the gyri at the fissure of Sylvius —namely, the inferior parietal lobule, the supramarginal and the angular gyrus. The destruction of the latter, especially in the left hemisphere, is generally associated with the special form of sensory aphasia, word-blindness or *alexia*. The patient sees the words, but cannot read them from a loss of his visual memory of symbols describing objects. In *paraplexia* he reads other words than those which he

wants to read. *Dyslexia,* which ought to be called dysanagnosia, was first described by Berlin, in 1883, as a disinclination to read, as if it were impossible to make the necessary mental effort. Such a patient is unable to read to himself or aloud more than four or five words; he then becomes exhausted. Vision may be perfect, and there may be no asthenopia from a refractional error. In six autopsies lesions were found in the left hemisphere, in Broca's region not far from the third frontal convolution.

The other kind of hemianopia, heteronymous hemianopia, embraces those cases in which either both temporal or both nasal halves of the visual field are wanting. Lesions of the central portion or of the anterior or posterior angle of the chiasm causes temporal hemianopia by affecting only the fibres that cross from the nasal half of each retina. Damage to both lateral angles of the chiasm causes nasal or medial hemianopia, by affecting only the non-decussating fibres. The latter is extremely rare. Monocular hemianopia is the consequence of lesion of one nerve in front of the chiasm or at one lateral angle.

## EVERY DAY SURGERY.*

P. O. KEEF, Oconto, Wis.

The surgeon of to-day cannot afford to treat the most trival injury carelessly.

The study of bacteriology shows beyond doubt, that wound infection is due to the presence of pathogenic germs which can be excluded by proper antiseptic precautions. This knowledge is not confined to the profession, but people know enough about blood-poisoning to ask some very embarassing questions when certain symptoms manifest themselves, and if a life or limb is lost the surgeon is liable to be defendant in a suit for malpractice.

It is only by a thorough knowledge of the causes of infection and by the most scrupulous attention to detail that we can do good, clean surgery. The wound or field of operation and everything which may come in contact with it, must be thoroughly sterilized. It is not sufficient to apply a pad of iodoform gauze or other antiseptic dressings over a wound, as they have no power to exert any influence over germs deeply seated—and they need not be very deep either, as the antiseptic must come in actual contact with every germ and remain so for some time to destroy its vitality. I have had a good many incised and lacerated wounds come under my care after they had been dressed elsewhere quite expensively in the matter of antiseptics, but the first and most important point, aseptisizing the part, was neglected or imperfectly done, as underneath the dressings the wounds were freely suppurating.

No doubt those men thought they were doing antiseptic surgery, and will in time either have their eyes opened to the fact that some of the details were lacking, or they will join the rapidly decreasing army of unbelievers.

The abdominal surgeon rarely infects the abdomen, much less should we have infection in our ordinary operations.

The laudable pus of our older teachers is a disgrace to the surgeon of to-day, and the law requires better work of the country doctor of the present time than it did of the city expert of twenty years ago. It seems to me that it ought to be almost impossible for the recent graduate to do unclean surgery, as he is taught so thoroughly by precept and example that he could not think of making or touching a wound without proper preparation. It is different, however, with the older men in the profession. Many of us were planting microbes before antiseptics were ever thought of.

We have to learn the new way and also to break ourselves of old habits, not an easy thing to do. I have been doing what I called antiseptic surgery for about twenty years, but until within about the last five years it was very unsatisfactory. The following report of cases shows the value of thorough asepsis and antisepsis, and that we may now expect to succeed in the most desperate cases.

*Read before the Wis. State Medical Society, May, 1893.

Case I. May 25th, 1891. Arthur B.; came to me on account of sore leg. He was terribly emaciated, had frequent chills; temperature 103°; pulse 130. I found tarsus and tibia entirely broken down, knee joint filled with pus, and on amputation between middle and lower end of the thigh, found pus in the medullary cavity. I curetted thoroughly with a sharp spoon and irrigated with 1-1000 sublimate solution, and after introducing a few strands of coarse catgut the whole length of the canal, I closed the wound with sutures leaving the ends of catgut protruding. An antiseptic dressing was applied, not to be removed until indicated by abnormal mal temperature. May 26th, temperature 101°; pulse 130. May 27th, temperature 98½°; pulse 100; eating and sleeping well. Temperature remained normal after this and patient improved rapidly, and on the fourteenth day the dressings were removed and the stump found to be entirely healed. The ends of catgut came off with the dressing, leaving a small granulating spot which healed in a few days. Patient went home three weeks after the amputation perfectly well.

Case II. Adam H., age 29 years, a Bohemian laborer, called me on June 6th, 1891, on account of an attack of appendicitis. I advised an immediate operation as this was the second attack within four months. He would not consent and I did not see him again until June 13th. He was then in very bad condition. Profuse perspiration; temperature 104°; pulse 140; severe pain in the lower part of abdomen, which was bulging and dull. His bowels had not moved for six days, enemas failing to bring away anything, and there was a constant profuse discharge of colorless glairy mucous from the anus. On the night of June 13th, he came to my hospital for an operation. The next morning his condition seemed much worse. There was uniform distension of the abdomen and patient seemed in a state of collapse. I operated immediately by an incision over the appendix, allowing the escape of gas, pus and feces. The incision was carefully enlarged upwards, the abdomen and pus cavity thoroughly irrigated, first with hot sterilized water then with a 1-3000 sublimate solution, followed again by irrigation with a large quantity of hot sterilized water. On examination I now found that the appendix had sloughed off and from this perforation the cæcum was torn allowing pus and feces to enter the peritoneal cavity. I sutured the edges of the torn intestine to the parietal wound and introduced a large and a small drainage tube to the bottom of the abscess cavity. The patient was now placed in bed and surrounded with bottles of hot water. Reaction was very slow. The cavity was irrigated with hot Thiersh's solution every six hours and it was not until the fourth day that any sign of improvement took place. He then commenced to gain and on June 29th, the abscess cavity was obliterated and I attempted to close the fecal fistula by paring the edges and suturing. The attempt failed as did several other attempts that I made. During the next three months I tried all the schemes I could think of, but each time after a few hours he would have severe pain and the fistula would burst open. I now proposed to unite the ilium with the colon to which he readily consented, and on October 12th, I made a median incision below the umbilicus and made an anastomoses of the lower end of the ilium and the descending colon by means of Senn's decalcified bone plates. The bowels moved naturally the next morning for the first time since his sickness began, and the fistula healed without any treatment except his wearing a pad of borated cotton pressed against it. I did not look for the site or cause of obstruction of the colon because just after making the abdominal incision as I was lifting out the intestine the patient became asphyxiated and I had to complete the operation as soon as possible. On account of the ilium opening so low in the colon I expected that the feces would be fluid, but I have asked the man about it a number of times since, and he says he is all right and as well as ever.

Case III. On June 27th, 1891, Thomas H., age six years, while playing in the barn fell with his knee on a scythe splitting the patella longitudinally from the center slanting outwards, so that it cut off about one-fourth inch of the articular surface and opened the capsule of the joint to the extent of one and one-half inches. The joint was filled with blood and hay seed and in order to properly irrigate I removed the smaller piece of patella and cleaned the joint thoroughly. The capsule and deep tissues

were sutured closely with fine catgut and the skin with silk sutures. A plaster of Paris cast was applied over the antiseptic dressing and left on for eight days. When removed the wound was entirely healed and passive motion made, which was slightly painful at first, but in a few days he began to walk with as good a joint as before.

Case IV. On September 27th, 1892, Mrs. C. G., age 28 years, was sent to me by Dr. Brett, of Green Bay. She began to have severe pain in the left side, in February, accompanied with chills and fever. When I first saw her she had lost seventy-five pounds in weight in seven months. She was still suffering severe pain and had slight chills. Her temperature was 101°, and remained so until I operated on September 29th. Dr. Phillips, of Menominee, who was present saw her at the Providence Hospital in Menominee about three months before, and said he could by pressure reduce the size of the tumor, by forcing the pus through the tubes into the uterus. An incision was made along the linea alba and the tumor found firmly adherent. It was carefully enucleated. During the operation a few drops of pus appeared to ooze from the tumor where a firm adhesion had been broken up, and I packed the abdomen with sterilized gauze in case of possible rupture. The remaining adhesions were broken up and the tumor successfully removed. The pedicle and all bleeding points were ligated and cauterized, and a large rubber drainage tube with a wick of iodoform gauze placed in Douglass' pouch and the abdominal wound closed. Two hours after the operation I gave $\frac{1}{3}$ gr. morphia which was the only dose required. Temperature in the evening was 100½°. Next day, September 30th, temperature 100°. October 1st, temperature 98½°. I removed drainage tube. The temperature remained normal after that and abdominal wound healed by first intention, except site of drainage tube which healed in a short time by granulation.

During her four weeks stay at the hospital, patient had gained twenty-two pounds in weight and has been well since. The tumor was between four and five inches in diametre, consisting of one large thin-walled cyst filled with intensely foul smelling pus, and a few small cysts filled with a transparent gelatinous fluid. The fimbriated extremity was firmly adherent to the tumor, but the tube itself was somewhat thickened but contained no pus. I do not report this case on account of its peculiarities but because one of the physicians present, quite a prominent surgeon, is reported to have said afterwards that the operation was uncalled for and that the patient could have been cured by other means. Now, if an operation is not called for in such cases as this—when should we operate?

Case V. Nov. 16, 1892, I was called to Gillett to see R. K., who on the evening previous received four bullet wounds from a 38 caliber revolver, in various parts of the body. One of them entered the abdominal cavity by passing through the left ileum about its center. It passed upwards and forwards and lodged in the left rectus. On cutting down on the bullet a few bubbles of gas escaped so the incision into the abdomen was completed and the intestines examined.

At one point in the small intestine there was some discoloration of the mesentery, and one side of the intestine had lost its glistening appearance. The descending colon was perforated and cut nearly half off, except a narrow bridge about ¼ inch wide between the two bullet holes. The mucus membrane was everted so that it completely filled both openings, preventing almost absolutely the escape of fecal matter, and I failed to force any out by pressure on the bowel until I cut the narrow bridge; thus nature had quite effectively protected the peritoneum and there was no hemorrhage to speak of. The wounded colon was repaired with a large number of Czerny—Lembert sutures. The peritoneal cavity was thoroughly irrigated and the abdominal wound closed. I left him 1½ hours after the operation feeling well and he continued so until about noon on Nov. 18th, sixty-fours after the shooting; he became restless; his temperature, which had been 99° to 99½° fell to 96½°, the abdomen began to swell and became tympanitic. I saw him about 3 P. M. and he was in a state of collapse. I supposed the sutures had given away.

He died about 10 P. M. just seventy-two hours after the shooting. Autopsy was made eighteen hours after death by Dr. Hinch, of Gillett, who kindly sent me sections of bowel. The sutured colon was perfectly united, but in the small in-

testine were found three small perforations about ⅛ inch in diameter—two on one side of the bowel about ½ inch apart, and one on the other side directly opposite to them. I made a post mortem diagnosis of embolism of a mesenteric artery and necrosis of the corresponding part of intestine, probably the part found discolored at the time of operation. I think in all cases where the mesentery is injured, the only safe plan is to remove a V shaped portion of the intestine and unite by anastomosis or other means. It may be that many of the deaths after gun-shot wound are due to slight injury to the intestine or mesentery which is either not seen or thought not to be of any consequence, instead of failure of the part operated upon to unite.

If a post-mortem had not been made in this case I would still think as I did when I saw him the last time alive, that the sutures had given away.

## FOREIGN SUBSTANCE IN THE EAR FOR THIRTY YEARS.

C. C. MOORE, M. D., PHILADELPHIA.

In March, 1892, F. L., æt. 73 years, came to my office for a troublesome winter cough so severe he could not rest at night. He had not laid down for some months, but slept in the upright position. This cough had been increasing for several winters and was apparently a case of chronic winter bronchitis of old age. He had not consulted any other physician though the coughing had been severe for some time. Objectively he was a large, strong man; respiratory sounds negative, pharynx red, congested from constant coughing, but I could detect no cause for it. Nares clear and mucous healthy. I clearly had a case of reflex cough. I looked in the left ear and it was normal in every way. He protested his hearing was perfect. I put the ear speculum aside, then thought I would complete the examination and look in the right ear, where a large piece cerumen that filled the canal was discovered. I removed it with the syringe and warm water. This revived his memory and he told me that thirty years ago, while driving along a woods, some insect flew in his ear. It annoyed him for about an hour, then suddenly quit; he gave this no more attention, but always thought his hearing was somewhat impaired on that side. Removing this substance cured his cough completely, for more than a year has lapsed since. In the centre of the cerumen was a grain of sand the size of a bird shot. This had formed the nucleus for cerumen. It had probably been thrown from the carriage wheel, and caused the sensation like the buzzing of an insect.

I consider the case exceptional, and it proves how misleading a symptom may be and that we can not always treat the symptoms. A cough, like a headache or neuralgia or pain, may be caused by disease remote from the locality of the annoying symptom.

### The Justifiable Prevention of Conception.

The physician not infrequently has to warn against conception in cases where a pregnancy would endanger the life or the health of the patient. Pelvic contraction, abdominal and uterine tumors, etc., form such an indication. The advice to abstain from coitus is but seldom followed, and the means usually employed to prevent gestation (mechanical) are objectionable from a hygienic and ethical point of view. Kleinwächter has endeavored to find a remedy which would have none of the aforementioned drawbacks. He prescribes a cacao-butter suppository containing 10 per cent. of boracic acid, to be introduced high up into the vagina. These suppositories dissolve in about one hour, and the liberated acid destroys the spermatozoa. Bichloride of mercury in 0.001-gramme doses can also be used, but in that case a vaginal douche has to follow the sexual act. The solvency of the suppository is heightened by adding one grain of oleum olivæ. The author considers this a safe and sure remedy to prevent conception. Therapeutic effects may be combined by the adding of various drugs—for instance, tannin in cases of uterine catarrh.—*Medical Age.*

# SOCIETY REPORTS.

## THE SURGICAL SOCIETY OF LOUISVILLE.

*Stated Meeting, May 8th, 1893.*

THE PRESIDENT, DR. A. M. CARTLEDGE, in the Chair.

### FATTY TUMOR.

DR. W. O. ROBERTS: This specimen is a fatty tumor which in itself does not amount to much, but the location from which it was taken makes it rather interesting. The patient was fifty-five years of age, and the tumor was first noticed three years ago; it was then quite small and was thought to be an enlarged gland in the carotid triangle of the neck. It has grown gradually. At the time of its removal, ten days ago, it had attained a considerable size and produced a good deal of discomfort from pressure upon the structures of the neck. It is the first time I have ever seen a fatty tumor in this locality, and for that reason I report the case. Hemorrhage, which would have been considerable, was controlled with clamp forceps. I was assisted in the operation by Drs. Joe Anderson, Beard and Block.

### DISCUSSION.

DR. E. R. PALMER: Did the tumor have any effect on the breathing?

DR. W. O. ROBERTS: It had begun to do so.

The essay of the evening was then read by Dr. E. R. Palmer.

### CARE OF THE UPPER AIR PASSAGES IN THE TREATMENT OF SYPHILIS.

Contrary to a quite common belief and mode of procedure, the scientific treatment of syphilis is anything but simple or stereotyped. Attention to what at first seem but little things constitute a very important part of the surgeon's duty. He has a great deal more to do than to simply order two years or more of constitutional treatment with a cessation from tobacco and alcohol. Among the other duties that devolve upon him, are frequent inspection of the nose, mouth and pharynx. The mere casual search for mucous patches in the latter two will not suffice. On taking charge of the case, he should familiarize himself fully with the pre-syphilitic topography of these parts. In so doing it will be a matter of surprise how frequently their condition is found to be a vicious one. Notably is this the case as regards the mouth. Scurvy, snags, or a general foul and so insanitary condition being frequently present, calling for correction. When possible, each patient, unless the mouth be found in an excellent state, should be sent at once to a competent dentist to have his teeth cleansed, filled, etc., and he should be ordered not only a good dentifrice with a soft brush and pure castile soap for daily use, but from time to time when any specific evidences appear, a mouth wash of listerine, zymocide or the like used, if possible, in full strength.

Enlarged or chronically diseased tonsils should be removed, and chronic non-specific catarrhal conditions of the pharynx being common, these parts must be brought into the best possible conditions by local and constitutional treatment. But of vastly more importance is the care of the nares. It is reprehensible in the extreme to wait until bloody discharges or bits of exfoliating turbinated bone tell the story of probably irreparable damage.

It must not be overlooked that while destructive, and so incurable, phases of syphilis usually attack the nares late in syphilis, they are also usually preceded by early and curable troubles that lay the foundation, when overlooked, for the final damage.

One object I had in calling your attention to this matter to-night is to urge in such cases, both as an exploratory and as a curative measure, the use, with a post-nasal syringe, of a combination in equal parts of Dobell's solution and 15 vol. peroxide of hydrogen. When trouble exists, the discharge of, sometimes, enormous quantities of decomposed muco-pus follows with a great sense of relief and comfort on the part of the patient. Pain is rarely experienced, and where it is, a one per cent. solution of cocaine snuffed from the hollow of the hand suffices for its relief.

While I do not urge this as a *one* remedy in nasal syphilis, I desire to add it as an important combination to the list already recorded. Gummata of the hard palate are usually of a tertiary character. I have recently relieved two such cases without perforation by heroic mercurialization and the application of saturated solution of silver nitrate daily — better results than are obtained usually by the mixed or pure iodide treatment.

A case recently under my care illustrates the necessity of close observation in upper air passage complications. An actress, leading lady of a prominent combination, came to see me with acute aphonia. She was greatly distressed, as she stated a surgeon of Johns Hopkins Hospital had told her her disease was syphilitic in character. She was vehement in her assertions that she had never had syphilis. On examination of her mouth I discovered an enlargement, median of the hard palate, gumma as large as an ordinary grape. I sent her to see Dr. Cheatham, who found no evidence of syphilis in her throat and soon relieved her. I saw her daily for about two weeks as also did Dr. Cheatham, and it was not long before we diagnosed the elevation to be a congenital deformity. The patient has since remained wholly well.

The other doctor diagnosed syphilis, probably, from the supposed gumma, not having made, as I learned, a laryngoscopic examination.

DISCUSSION.

Dr. W. O. Roberts: In regard to peroxide of hydrogen in the nasal douche, I tried this on two cases and it produced such discomfort that I had to stop it. However, in these cases I used Marchand's peroxide of hydrogen. I have since used the Oakland Company's, which did not produce any of these disagreeable effects. I would like to ask Dr. Palmer if he does not think the douche would answer the same purpose as the post nasal syringe? I rely chiefly in the management of these cases upon constitutional treatment.

Dr. E. R. Palmer: The thing is to get them to use it. In cases of early syphilis, I have removed from the nostrils sometimes a double handful of muco-purulent material by throwing the syringe twice full up over the velum palati. I have never seen any inflammatory trouble follow use of the syringe. I use the O.C. peroxide solely.

Dr. Wm. Cheatham: I remember the case Dr. Palmer refers to very well. I did not believe it was a node or gumma. I saw an article a short time afterward where a gentleman reported a lot of these congenital projections.

I think Dr. Palmer's solution of peroxide a little strong; it is liable to be forced into the middle ear and up into the sinuses. I think he will find that a 2 or 3 volume, will do just as much good and is much safer. Another precaution I would like to call Dr. Palmer's attention to, is that of blowing; if you have the patient blow, some of the secretion or solution is very liable to get into the middle ear. Always after using spray, douche or post nasal syringe, let them draw it down instead of blow, thus avoiding danger to the ear.

Dr. Roberts asked about the douche. No anterior treatment reaches more than two-thirds of the nose. Where a solution is used anteriorly, either with spray or douche, it does not reach over the turbinates, but if you use it posteriorly it does. Men write a great deal about syphilis of the upper air passages, I do not think I I have but one case now; syphilis shows about one-third the way back in the right nose in this case, which I have relieved by chromic acid. I think it was gumma; had primary lesion four or five years ago. In late syphilis I find cod liver oil very beneficial.

Dr. A. M. Cartledge: I suppose my experience is like that of most other physicians; I find some cases recover very promptly under treatment while others are very obstinate. I formerly used nitrate of silver nearly altogether. In the last year or so I have been using gargles or mouth washes of mercury bichloride, using it as part of the treatment. I think bichloride wash, just as a sanitary measure, is a good thing. Many of these cases demand other things than iodide of potassium; as a rule I think we neglect the general building up of these people too much. I believe, in the late manifestations of syphilis, quinine, cinchona, cod liver oil, etc., may be given with excellent results.

Dr. E. R. Palmer: I am surprised that Taylor, in his work in Hare's System, objects to the use of the black wash in syphilitic troubles. He says that in private practice it nauseates his patients, but in the Vanderbilt Clinic he gets very fine results from it. I think a great deal of the black wash

and advise its use in suitable cases. It was more to call attention to the matter of mouth hygiene than anything else that I prepared the short paper read this evening.

In the matter of cod liver oil—as most of you know, I taught lung diseases for sixteen years, and I believe that benefit may be derived from the administration of cod liver oil vastly more in late syphilis than in phthisis. I prescribe it nearly every day; there are three or four favorite preparations among the emulsions and I give them, feeling absolutely certain that beneficial results will follow. My faith has very materially weakened in regard to the iodides; I do not get results from them such as I would like or would expect, considering the reputation they have had.

I want to mention two other cases in addition to those referred to in the paper, where I have recently relieved gummata of the hard palate by the administration of three to five grains of proto-iodide daily and daily application of nitrate of silver; both cases were completely cured without any destruction of the bone. One of the patients was a terrible acne subject; had been to Hot Springs twice; he could not take iodide of potassium without its producing very distressing conditions, tumefaction, tormina and all the other disagreeable symptoms. I gave him cod liver oil and he was then able to take the treatment without any trouble.

The next case was double infection. While he was being treated for tertiary syphilis, contracted in 1885, he got a fresh case. While under treatment for this new syphilis, he developed a gumma of the hard palate. He was given four or five grains of proto-iodide daily and, with the application of silver nitrate, got entirely well. I do not give iodide of potassium in conjunction with cod liver oil. I think iodide should be used singly, but my results in its use are not very encouraging except in brain and bone syphilis. In such cases iodide is indicated sometimes to the Hot Springs extreme, 120 grains three times a day or even more will be found very beneficial.

Dr. Wm. Cheatham: I would like to call attention to the fact that in some severe cases of secondary syphilis of the tonsils, pharynx and inside of cheeks, constitutional treatment appears to have but little effect, until the above lesions are relieved by local treatment. I use in such cases the "black wash" or hydrogen peroxide (Oakland Co.) 10 vol., six ounces; glycerine two ounces; hydrarg. bichloride one grain locally. I do not know how to explain this, but I know it to be a fact.

Dr. H. H. Grant: I would like to ask Dr. Palmer if he uses mercury hypodermatically in the treatment of syphilis.

Dr. E. R. Palmer: I have never employed mercury hypodermatically. I think injections might be used simply for their local effect. For instance, some men inject gummata and nodes in the treatment of syphilis with view of getting the local effect of the agent. It has never become a part of the treatment in this country. It is exceedingly painful and has not done the work it was claimed it would do. I think this is the reason why the hypodermatic use of mercury has not become more general. It was claimed that by this means in a three months' course of injection, syphilis could be eradicated from the system. I do not believe this will ever be the case; you must treat your patient over a considerable period of time, no matter what agent you use or the manner of introduction.

Dr. H. H. Grant: Do you not think that the good effect derived from the administration of cod liver oil is owing to its constructive powers, aiding the constitution to avert or overcome the tertiary manifestations, thus rendering iodide unnecessary?

Dr. E. R. Palmer: I do not see how we can well explain the wonderful results obtained by the use of cod liver oil. I hardly think it can be explained by the small amount of iodine it contains.

Dr. A. M. Cartledge: Do you not think that mercury when applied to the local manifestation of syphilis, has a local specific effect?

Dr. E. R. Palmer: Unquestionably it has. The action of mercury is as a solvent of the neoplasm, and this is where I would favor injection, in pronounced lesions, of the gummata to get the local effect of the mercury. The point I wished particularly to emphasize, is the care of the mouth; that it is not sufficient to look into the mouth for mucous patches, etc. You would be surprised at the number of people that present themselves with the most horrible mouths. Scurvy is a very common condition; teeth loose, breath foul, gums

bleeding and all those other conditions that make the mouth look more like a cess-pool than the sweet, clean organ that it should be. Another point I want to emphasize is that the physician should familiarize himself with the presyphilitic topography of the case.

In the case of the actress with the growth in her mouth; if the mouth had been carefully examined previously she would have been familiar with the true nature of the trouble there. She was not even able to tell how long this growth had been present.

In this connection I would like to mention that I saw to-day a lady who had the change of life ten years ago, a wonderfully well-preserved woman, with the two tonsils as large as you will see in very much younger subjects; two immense tonsils almost meeting in the pharynx. I was laboring under the impression that the tonsil atrophied in old patients.

DR. WM. CHEATHAM: Such conditions are not common.

CONTINUED REPORT—(PARTIAL THYROIDECTOMY).

DR. A. M. VANCE: I would like to make a continued report: At the last meeting of this society I presented a specimen consisting of a portion of thyroid gland removed a few days previously. At that time I read a letter from Dr. Louis Frank, written me after he had made a careful microscopical examination of the growth, in which he pronounced it thyroid gland. You will remember at that time there was some doubt expressed by one or two members as to the nature of the tumor, that is whether it was really thyroid tissue. I have since had it examined by several other microscopists and they all agree with the report made by Dr. Frank. I will read their several letters, also a short report from the *New York Medical Journal*, and a quotation from the *American Text Book of Surgery*, bearing on the question.

"PARATHYROID GLANDS IN MAN."

"At a meeting of the Paris Medical Society of the Hospitals, held on March 17th, reported in the *Union Medicale* for March 21st, Dr. Chantemesse and Dr. Marie described some little glandular organs found in the neighberhood of the thyroid gland in man, and confirmed Sanderström's description of parathyreoid glands. They form two groups, one of which, the more important, is situated at the level of the point of penetration of the inferior thyroid artery. This group consists of two or three glandules, none of them larger than a lentil, round, ovoid, or kidney shaped. The other group, generally less voluminous, is at the level of the point of penetration of the superior thyroid artery. These little glands are free or surrounded with connective tissue and provided with a minute vascular pedicle. Their structure is very different from that of lymphatic ganglia. They are divided into lobules by a connective tissue stroma, and are traversed by numerous capillary vessels. The lobules are formed of little cells sometimes disposed irregularly, sometimes arranged in a circle, the periphery of which is bordered with little cubical cells. and the centre filled with irregularly disposed elements. Occasionally, true tubes of epithelial cells may be made out, and at the periphery of the glands there are often to be seen little rounded masses, the central part of which contains a material having a colloid appearance. Stress was laid on the fact that these glandules were situated externally to the capsule of the thyroid gland, and it was urged that they be left in cases of thyroidectomy, for they were capable of a compensatory function analogous to that of the pituitary gland."—(*N. Y. Medical Journal*, April 15th, 1893.)

"The body is quite likely to be accompanied by accessory masses of similar tissue, which may be connected with it or may lie behind the trachea, or beneath the base of the tongue, or elsewhere about the middle or anterior portions."—(*The American Text Book of Surgery.*)

"DR. A. M. VANCE: I agree with Dr. Frank's statement, having made a microscopic examination of tissue and would like to add that I believe it to be not only thyroid gland tissue but a goitre."

DR. WM. VISSMAN."

"MY DEAR DOCTOR VANCE: "I was requested by Dr. Rodman to examine a piece of tissue unaccompanied by clinical history, etc. I did so and after examining ten or twelve sections reported it as thyroid tissue. I presume this is the same tissue examined by Drs. Frank and Vissman and if so, I concur in their diagnosis." Respt.

H. M. GOODMAN, M. D."

"My Dear Doctor Vance: "At the request of Dr. Goodman, I examined a section of the tissues above described, and found it to present all the characteristics of thyroid tissue."

Yours very truly,
H. A. Cottell, M. D."

"Dear Doctor Vance: "Macroscopically and microscopically I think the tissue sent me by you to be a thyroid gland."

Respt.
Jno. L. Howard, M. D."

"Dear Doctor: Just coming home I found your note requesting me to give you my statement in regard to the specimen examined for Dr. Rodman and I gladly do so, as I have done at the time to him. The piece of tissue handed to me by Dr. Rodman was partly dried at the outer surface and consisted of two sorts of tissue to the naked eye, one grayish and glistening, the other a small nodule at the periphery, a yellowish white firmer tissue.

Microscopic examination shows the tissue to be made up of gland-acini, varying in size from $\frac{1}{25}$ to $\frac{1}{500}$ inch, irregular in outline, separated from one another by a delicate fibrous wall, and lined with roundish nucleated cells somewhat larger than the ordinary lymph corpuscles. In some of the larger acini, the lining cells are flattened by compression of a clear homogenous refractive substance filling the acini (colloid material), some few of the acini are filled with an organized tissue made up of a delicate connective tissue, some others have a yellowish brown pigment lying within the colloid material.

The mentioned yellowish white portion is made up of densely packed alveoli which are filled partly with colloid material but the majority with densely crowded cells of the same type as those lining the wall. The stroma is supplied with a moderate amount of small blood vessels.

As to "the resume"—I have not the least hesitation or the slightest doubt to state, as I have done to my friend Dr. Rodman, that the specimen in question is a piece of thyroid gland in a state of (very common in this structure) colloid degeneration, or as you find it named by German pathologists Struma Colloides.

Hoping to have served you by this report"

I am sincerely your friend,
C. Weidner."

Dr. Frank has made several sections of the growth, which I have had him bring here this evening and would be glad to have you examine them through the microscope, also compare them with other specimens of thyroid tissue.

Dr. W. L. Rodman: I wish to add a word in regard to Dr. Weidner's opinion: Dr. Vance was kind enough to give me a portion of the specimen; I had it in my buggy and in driving down town met Dr. Weidner, who said he would be very glad to examine it. He made an examination and made the same report to me verbally that he has in writing to Dr. Vance. I take pleasure in stating that Dr. Weidner further said he was not certain, but the point in the section he made there seemed to be cells of a sarcomatous nature. I do not mean to quote the doctor as saying that it was necessarily sarcomatous degeneration of the thyroid, but he found cells looking very much like sarcoma cells. I stated at the last meeting that if this was thyroid tissue, I was satisfied that it was an accessory thyroid that occurs occasionally at different points in the neck, sometimes inside the larynx and trachea, and when they do occur, they are subject to the same enlargements as the thyroid-cystic degeneration and fibrous bronchocele.

From the unanimity of the report made by the microscopists, I am satisfied that this must be thyroid tissue. I am still under the impression, however, that it is an enlarged accessory thyroid, as the isthmus is very infrequently the seat of goitre, it nearly always affecting one of the two lobes, preferably the right. Hypertrophy of the isthmus is very infrequent. In a paper that I am now preparing, which will be read at the next meeting of the Kentucky State Medical Society next Thursday morning, I take up diseases of the thyroid as well as other tumors of the neck. I have gone over the literature very carefully, and am, therefore, in position to speak advisedly upon the subject. Benign solid growths practically do not affect the thyroid gland, the only one being the fibrous bronchocele or hypertrophy of the gland. Cystic degeneration is frequent. As to malignant growths: Kaufman, in an elaborate paper on the subject, was able to collect only 21 cases of carcinoma affecting the thyroid, and 7 cases of sarcoma. So I think I was right

in stating that benign growths of the thyroid are practically unknown, and that malignant growths are very rarely found, so rarely that I doubt if any member present has ever seen one.

Dr. Louis Frank (Visiting): I was asked by Dr. Vance to bring some sections (of the specimen handed me by him) here to-night to demonstrate the correctness of my diagnosis. His report from the other microscopists of the city was entirely unsolicited by me. I intend to stand on the report I have already made. Some one has mentioned the short time consumed by me in making an examination of this tumor. I will state that, as the specimen was fresh, no time was required further than to make a few sections of the growth and mount them for examination, probably ten or fifteen minutes.

Possibly I misunderstood Dr. Rodman in saying that non-malignant growths of the thyroid were very infrequent; from my reading (and I have looked over two or three books on pathology since this tumor was sent to me), I find that cystic growths of the thyroid, what we ordinarily term struma, are quite common. I agree with Dr. Rodman that malignant growths of the thyroid are very rare, comparatively few cases being on record. Benign growths, though, are very frequent, being either of the cystic variety or being fibroid in character; the latter variety being usually a result of changes following hemorrhage of the cystic tumors.

Dr. H. M. Goodman (Visiting): I have very little to add to the foregoing remarks, except to define my position in connection with the examination of the specimen. I worked under very adverse circumstances. I knew nothing about the case; a piece of tissue being handed me by one of my colleagues at the University with the request that I examine and report upon it. I remarked at the time that it was a very difficult thing to do in the absence of any clinical history, but as the tissue seemed to be tolerably hard and firm I immediately embedded it in colloidin, and made a few sections and proceeded to examine it. The first section showed thyroid tissue with increasing amount of colloid material in the sacs of the tissue. I am glad, for once, the microscopists of the city seem to be agreed, and certainly I think the diagnosis is absolutely settled. I will add, however, that in sending the report to Dr. Rodman, I made the diagnosis of colloid struma.

Dr. Louis Frank: I would also like to say that it is only by microscopical examination that we are able to recognize certain tissue macroscopically. It is the microscope that renders us able to know certain tissues, and that has by analyzing structures enabled us to say what they are when we next see them. Were it not for the microscope we would never be able to recognize carcinoma or any other growths macroscopically.

Concerning the point made by Dr. Goodman in regard to the clinical history: The specimen was handed to me with no history whatever, except that the tumor was removed from the neck, consequently the question of clinical history did not figure in my diagnosis. You cannot always rely upon the clinical history for diagnosis.

### RIB RESECTION FOR EMPYEMA.

Dr. W. O. Roberts: I will report a case I operated upon at the University Clinic last Tuesday morning. A man, thirty-five years of age, sixteen years ago had what was said to be pneumonia of the right side; had never been well since. Five years ago, a large swelling appeared just above the edge of the cartilage on the right side and it was finally opened, discharging very profusely and has been discharging freely every since. Upon examination, I found the left side of the chest enlarged and the right side perfectly flat and dull clear up to the point of the scapula. I made an incision down to the seventh rib on a line with the posterior diameter of the axillary space, found the ribs so close together that I could not get anything between them. I then resected a portion of the seventh rib, removing a piece probably about two inches in length. I then opened the chest and I think the foulest pus that I have ever smelled in my life came out. There must have been at least a pint of it, if not more. I inserted a large drainage tube without washing out the chest, emptying it as thoroughly as I could by changing the position of the patient, and sent him to the Sts. Mary and Elizabeth Hospital. He has gotten along without an untoward symptom and now the original opening is almost entirely closed. Nothing comes out of it.

I report the case as being of interest because of the fact that this condition of empyema has lasted such a length of time. He dates it back sixteen years; has never been able to breath well on that side since the attack of pneumonia.

DISCUSSION.

DR. A. M. VANCE: I would like to ask Dr. Roberts why he did not wash out the chest?

DR. W. O. ROBERTS: Because of the fact that a number of sudden deaths have resulted from washing out the sac in cases of pyema, especially cases where the empyema was on the left side.

DR. A. M. CARTLEDGE: I hope a continued report will be made of this case, I do not think the man will get well. A lung compressed by an accumulation of pus for sixteen years will not get well as a rule with the resection of 1½ to 2 inches of rib. The case is of such long standing, there is evidently a quantity of old fibrous tissue existing, and I do not believe there will be sufficient lung expansion to fill the cavity. I think there will be a discharging sinus requiring a more extensive operation. That has been my experience. The lung will not expand, and you will have to take out a section of two or three ribs, and break up adhesions that bind the lung down

DR. W. O. ROBERTS: This is the second case I have had where this offensive pus existed; both of them were operated upon at the University Clinic. The first case was several years ago. The man had been shot, the ball entering the upper part of the right side of the chest, between the third and fourth ribs, and had been discharging for something over a year; whenever he would lie down the pus would run out through the opening. I removed a section of the seventh rib and such offensive pus escaped that almost all the students left the lecture room. Referring to what Dr. Cartledge has said about the case just reported: I made the same remark at the time of the operation. However, I thought it was best to try it with the resection of one rib, and if I failed to get closure, then do the operation he refers to.

I saw in Edinburgh, in 1886, a case that had been operated upon by Annandale for empyema which had existed for years, and it seemed to me that he removed the greater part of one side of the thorax. He made an incision very low down and removed fully four inches of the tenth rib, a little less of the next and so on until the apex reached about the third rib. He told me he had operated on several cases in that way and had gotten excellent results.

DR. A. M. CARTLEDGE: Do you not think the odor, where the empyema has been the result of original pneumonia, is because of the fact that air has been introduced from the lung? I have seen several cases of this kind.

DR. W. O. ROBERTS: I am satisfied that there was communication with the lung in this case. Before the operation this man expectorated large quantities of pus that looked tuberculous in character. I am very sorry that I did not have a microscopical examination made of it before this meeting. Since operation, expectoration has diminished very much.

One peculiarity about this patient is that he has the most marked "club fingers" that I ever saw.

EMPYEMA—RESECTION OF RIB WITHOUT ANÆSTHESIA.

DR. A. M. VANCE: I would like to mention a case of empyema that I saw the other day. I was called by Drs. Rudell and Evans to see a little boy who had been sick for five weeks, beginning with pneumonia and ending up with what was supposed to be pleurisy of large proportions. He remained on his right side with the arm extended above his head; had been in this condition for about two weeks and unable to breathe comfortably in any other position. He was unable to turn over and all the windows had to be kept open in order that he might get sufficient air. We first gave him some whiskey and a hypodermic injection of nitro-glycerine, which improved his forces a little, and I found the whole right lung dull. I inserted an aspirator needle and drew off about an ounce of pus, then the needle became obstructed. I then determined to open the chest without any anæsthesia. I made an incision fully three inches long and inserted two large size drainage tubes; about a gallon of pus escaped, much of it being caseous in nature. As soon as about half of the pus was removed, the boy became very cheery and seemed much better.

The point of interest in the case is that the prolonged pressure seemed to have produced complete anæsthesia of the whole side. I would have washed out the cavity, had it not been for the fact that the boy was so much exhausted that I could not.

DISCUSSION.

DR. A. M. CARTLEDGE: I do not think we are justified in taking the additional risk in washing out the chest in these cases. In the first place, you have a large purulent sac that cannot be thoroughly cleansed by irrigation, and I think the attempt is attended with danger. If it were possible to render this whole surface aseptic, then we might afford to take the additional risk. No matter how thoroughly you empty an empyema sac, when the dressings are changed you will find them saturated with pus. I believe the best plan is to introduce the shortest drainage tube that will reach the cavity, not attemping to get to the bottom, then apply an antiseptic dressing and let the drainage take care of itself. In my opinion we will shortly have an entirely new pathology of empyema. Pleuritic effusion becoming purulent, simply means the introduction of infection through the lung; that most of these cases of pleuritic effusion follow as a result of pneumonia is beyond question. It is a well known fact that in the tuberculous variety, no mattter what means of drainage you employ, the patient usually dies.

---

**Don't Pick them Green.**

Statistics are said to show that young men do not, on the average, attain full physical maturity until they arrive at the age of twenty-eight years. Prof. Scheiller, of Harvard, asserts, as a result of his observations, that young men do not attain to the full measure of their mental faculties before twenty-five years of age. Better say thirty. A shrewd observer has said that "most men are boys until they are thirty, and little boys until they are twenty-five"; and this accords with the standard of manhood which was fixed at thirty among the ancient Hebrews and other races. A remedy is needed for the progress and propagation of puerility.—*Exchange.*

---

It is hard to feel at home with people who never make mistakes.

DR. KLEIN, the distinguished lecturer on physiology at St. Bartholomew's, has announced that science is enriched by a medical discovery as important in the domain of therapeutics as chloroform, laudanum and quinine. The great theory of infection by bacillus forms requires, in order to be fruitful of benefits to mankind, the discovery of a powerful germicide. In carbolic acid, in corrosive sublimate and in potassium permanganate, science has made long strides in the direction of adequate antiseptics and bacillicides, but these drugs all have their drawbacks. Now, however, Mr. Worrall, a noted scientist, claims to have found among the coal products a disinfecting body apparently superior to all previous ones. He has named it izal, and Dr. Klein, after a series of exhaustive laboratory experiments, is said to have found it absolutely destructive of the spores of some of the most intractable and malignant diseases. Unlike most powerful disinfectants, it is non-poisonous to human beings, and may be taken internally, diluted. Dr. Klein's experiments go to prove that, diluted with 200 parts of water, izal absolutely destroys the vitality of the microbes of diphtheria, scarlatina, glanders, erysipelas, typhoid and cholera. *Black and White,* in speaking of the discovery, says: "It is not too much to say that izal, unless the conclusions of one of the most competent of our physiologists are erroneous, is the most important discovery in practical therapeutics made during the present generation."

ISSUED EVERY SATURDAY

ADDRESS
Care P. O. Box 843, Philadelphia.

HAROLD H. KYNETT, A. M., M. D.,
Editor.

RODERIC C. PENFIELD,
Publisher.

316-18-20 North Broad Street,
PHILADELPHIA.

**TERMS**:—Five Dollars a year, strictly in advance, unless otherwise specifically agreed upon. Sent three months on trial for $1.00.

**REMITTANCES** should be made payable only to the Publisher, and when in sums of Five Dollars or less, should be made by Postal Note, Money Order or Registered Letter.

**NOTICE TO CONTRIBUTORS**:—We are always glad to receive articles of value to the profession, and when used they will be paid for, or reprints supplied, as the author may elect. Where reprints are desired, writers are requested to make a note of that fact on the first page of the MS. It is well for contributors to enclose stamps for postage, that the articles may be returned if not found available.

SATURDAY, JULY 22ND, 1893.

## EDITORIAL.

### TETANUS; ITS CAUSE AND CURE.

In 1884, Nicolaire (*Deutsche Medical Wochenschrift*, No. 42, 1884), produced tetanus in certain of the lower animals by inoculating them with garden earth. He also showed that the disease could be transmitted to other animals by inoculating them subcutaneously with the pus from the infected animal. Later it was shown by Carl and Rattone that it was an infectious disease, and could be transmitted from man to animals by inoculation. The bacillus was isolated and obtained in pure culture by Kitasato in 1889. Tetanus has been produced by a large number of investigators by inoculating animals with garden or field soil. So numerous have been the cases of tetanus in man from injury, and the test inoculation of guinea pigs with soil, that the bacillus is now known to be very widely distributed in nature.

Morphologically, the bacillus of tetanus is an exceedingly interesting germ. It is a slender rod-shaped germ with one end rounded and the other usually much enlarged, and containing a spore. The spore appears at the end in the form of a little sphere, giving the bacillus the appearance of a short pin. The bacilli are from two to three micromillimeters in length. They stain with the aniline dyes usually employed in staining bacteria, and they retain their coloring matter when treated after the Gram method. They are motile.

The bacillus of tetanus does not grow in an atmosphere containing oxygen. In anærobic cultures it develops at the room temperature, but grows best at a temperature of about 36°C. It liquifies gelatine and solidifies blood serum. In an atmosphere of hydrogen it grows very rapidly in alkaline bouillon and in gelatine. The addition of glucose to the culture medium increases the rapidity of the growth. The spores of tetanus bacilli retain their vitality for several weeks in a desiccated condition. They also resist a temperature of 80°C. maintained for an hour. They are rapidly destroyed by boiling. Experiments have shown that

when animals are inoculated with tetanus bacilli, either in pure culture or otherwise, that the bacilli remain at the seat of inoculation and that death results from the action of poisonous substances elaborated by the growth of the bacteria in their place of injection. Kitasato has shown that cultures of the tetanus bacilli that were filtered through porcelain, which removed all of the bacilli, would produce the disease; *i. e.*, symptoms and death. The result of certain European investigators show that this germ does not become attenuated by artificial cultivations. Biegor, Fraenkel and Kitasato have isolated a toxalbumin from cultures of the tetanus bacillus, which is very fatal. Much work has been successfully done in producing immunity in mice and guinea pigs against tetanus.

With the better knowledge of the disease has come a better method of dealing with it, and we now have authentic reports of the healing of traumatic tetanus by the use of the antitoxin of tetanus, prepared by Lizzoni and Cattani.

Schwarz (*Centralblatt f. Bakteriologie*, X. 1891), reports a case of traumatic tetanus that was cured by the use of subcutaneous injections of an emulsion of *antitoxin*, prepared from the blood of a dog that was immune to the disease. A boy of fifteen years was injured August 20th. Early in September he showed symptoms of tetanus, and September 17th was taken to a hospital. He exhibited every symptom of tetanus. September 18th, he received 15 grams of antitoxin; it was ground up in 3cc. of water and injected. September 19th, the injection was repeated in the morning and in the afternoon a second injection of 2 grams. September 20th, a marked improvement in the symptoms, in the afternoon 0.25 gram injected. September 21st, still further improvement, injection repeated. September 22nd, patient continued to improve; no injection. September 23rd, nearly recovered; the tetanus symptoms entirely gone. October 1st, the patient had fully recovered and was dismissed from the hospital. After each injection there was a depression in the temperature and after that a certain amount of perspiration.

Pacissi (*La Reforma Medica,* No. 4, 1892), reports a successful treatment of tetanus with the antitoxin (prepared from the serum of an immunized dog). After eight injections of the antitoxin the symptoms were relieved.

Several other cases of similar success in the use of this substance are reported, but they all tend to the opinion that the substance is practical and could be used with advantage in all cases of traumatic tetanus. The preparation of the antitoxin requires a certain amount of care and knowledge of chemistry and bacteriology. The results that are being obtained with this and other substances, prepared either from cultures of bacteria or the blood of immunized animals, suggest the importance of state boards of health equipping themselves with a laboratory and bacteriologist competent to prepare these substances for the needs of the physicians within their jurisdiction.

LOCAL ANÆSTHESIA may be readily produced in about a minute by a spray of menthol, p. j; chloroform, p. xv; and will last from two or six minutes.

# TRANSLATIONS.

## CLASSIFICATION OF ARTERITIS.†

Circumscribed arteritis, according to Lancereaux (*Le. Bull Mèd.*, March 29, 1893), has for its principal characteristic the circumscription of the arterial lesion, its localization to a vessel of medium caliber, its termination by obliteration or by aneurismal dilatation. It comprises three distinct varieties, syphilitic arteritis, tubercular arteritis, and embolic arteritis. The first two varieties, due to a general infection of the organism, are perfectly defined; the third, produced by the action of a foreign body, is no less clear, notwithstanding its varied origin, in its manifestations and its evolution.

*Syphilitic arteritis* is localized to the arteries supplied with lymphatic glands, and particularly to the cérebro-spinal arteries; whilst the other vessels and notably the large arteries, as the aorta and its principal branches, are slightly or not at all exposed. Several authors, however, have described syphilitic lesions of the large vessels. Weber reports that he has seen tumors of considerable size developed in the thickness of the middle tunic of the pulmonary artery together with gummy tumors upon the skull and in the liver. The circumscription of this lesion favors syphilis, but it is necessary to investigate further its evolution in order to positively admit its specific origin. In a case reported by Virchow, that of a young syphilitic girl afflicted with interstitial nephritis and whose aorta was garnished with sclerotic plaques, Lancereaux does not hesitate to recognize, in spite of the age of the patient, the existence of ordinary atheroma. He finds the proof of this in the multiplicity of the lesions of the aorta and in the nephritis which accompanies them. Most of the other cases of alteration, or of aneurism of the aorta attributed to syphilis, have no more value than the preceeding, because they are not based upon the proper characteristics and a special evolution, but only upon the false adage: *post hoc propter hoc*, if not upon the amelioration of the phenomena of aneurism subsequent to specific treatment, as if this treatment could repair a destruction of the arterial wall. Lancereaux believes that a certain number of these cases have a malarial origin. The frequency of alterations and aneurism of the large vessels, in the British Army and Navy, has for a long time attracted the attention of the English military surgeon. Welch concludes wrongly that this affection is due to syphilis. It should be remembered that the frequency of this affection is relatively larger among the colonial troops who are much exposed to a malarial infection, and Lancereaux is led to believe that the frequency of aneurism in the English army is due neither to syphilis nor to alcoholism, but rather to paludism, a disease equally as common among the troops and which has a tendency to produce a special aortitis.

The influence of syphilis upon the arteries, especially those of the cerebro-spinal centres is incontestable, these vessels, are in truth, the seat of predilection of the action of the syphilitic virus, and the reason of this lies in the lymphatic glands that surround them, for it is known that the lymphatic system is the avenue of the development of the manifestations of constitutional syphilis. The lymphatic becomes enlarged and pressing externally and internally upon the middle coat of the artery, the latter atrophies, and the blood, pressing upon the thinned wall, produces a simple dilatation or a true aneurismal tumor. In the other cases, the syphilitic arteritis produces a narrowing or even an obliteration of the caliber. These are followed, in either case, by an ischemia more or less complete, and often a rupture of the vessel.

*Tubercular arteritis* is relatively rare, but it likewise tends to become localized in the arteries of small and middle size and especially in those that possess a lymphatic adventitia, as the lymphatic medium is necessary to the development of the cerebral arteries. It shows a special predilection for the cerebral arteries and especially for the branches of the pulmonary arteries. Histolgically, it consists in an infiltration of the arterial

† Translated for THE MEDICAL AND SURGICAL REPORTER by W. A. N. Dorland, M. D.

tissues with granulation tissue. The external tunic, the beginning point of the process, is filled with round cells (embryonal cells), forming islets more or less voluminous, which invade the normal tissue little by little and in which may be found the so-called giant cells. This tissue degeneration becomes necrotic and ulcerous, and thus eventually dilatation or aneurismal tumors are formed. This terminates by obliteration, aneurismal dilatation or by rupture. The aneurisms in the lung are usually found in cavities, are single or multiple, and may be mixed, saculated or varicose, in their nature. Tubercular arteritis is an insidious condition and one difficult to diagnose.

*Embolic arteritis* has for its usual seat the branches of the pulmonary arteries and the cerebral arteries. The foreign body is surrounded by a development of embryonal cells due to the inflammation produced, a fibrinous clot forms and the calibre becomes obliterated by inflammatory action. The tunica intim takes on a vegetation and produces an endothelial bed and this tends to produce the obliteration, which is the most common termination. At other times ulceration occurs and aneurismal tumors are formed.

## APPENDICITIS AND ITS COMPLICATIONS FROM A SURGICAL STANDPOINT.*

The author, Dr. G. Lennander (*Upsala Läkarefören Forhandl*, bd. xxviii, Hft. 1.), reports 34 operative cases, which were operated upon by him and his assistants between the fall of 1888 and summer of 1892. There was but one death, which took place 5 weeks after the operation, caused by pyæmia, a small gangrenous portion of the intestines having been overlooked during the operation. In 3 cases, laparotomy with extirpation of the vermiform appendix was performed, in which diffuse peritonitis existed.

In 3 other patients, suffering from appendicitis, there were found 2 or more incapsulated intra-peritoneal abscesses, which were opened and drained; in only 2 of these was it possible to remove the vermiform appendix; of these 3 it was found necessary to make incisions through the vaginal vault and the colon.

In 12 cases, abscesses were found in the iliac fossa and in the lumbar region, and opened at those places; 3 times extirpation of the appendix; of the 9 remaining, 3 have had returns and there was 1 death, which has been reported at the beginning.

In 7 cases laparotomy and amputation of the ulcerated or gangrenous appendix; operation 40 to 60 hours after the beginning of the attack with the exception of 2, in which the attacks had lasted four days in one, and in the other nine days. Pelvic abscesses were present in 3 cases, 1 having discharged through the vagina and 2 through the large intestine. Amputation of the vermiform appendix was performed five times during the free intervals. Chronic appendicitis was diagnosed in one case, and operation revealed an abscess of the appendix, while the adhesions between the ileum and the anterior wall of the abdomen were dense; these were released during the operation.

As far as the author has been able to follow his cases, the patients are all well; three still remaining under observation. During this time two patients who refused operation died of gangrenous appendicitis; one had an inoperable carcinoma at the head of the colon and the other was supposed to be suffering from a perforating ulcer of the stomach, this presumably giving rise to the existing peritonitis. Etiologically, the author speaks first of foreign bodies or fecal calculi; the latter, according to his idea, forming in the appendix (not in the cæcum as Talamon teaches); further, he believes in the possibility of a retention of the secretions, aided by the swelling of the mucous membrane, and particularly assisted by a bend or constriction of the bowel.

The author has observed this in one case in which he operated, and later was able to palpate it in two cases before the operation. The primary stercoral typhlitis was observed by the author in several cases and he is therefore inclined to take the

*Translated for THE MEDICAL AND SURGICAL REPORTER by Marie B. Werner, M. D.

opposite view of Sahli. Severe repeated attacks of appendicitis, in which the pathological changes have been entirely confined to the vermiform process, and suppurative peritonitis, in which there were only catarrhal changes in an unperforated vermiform appendix, were also seen by the author. Lennander prefers the rectal and vaginal examination. He has, in several cases, found the difference in temperature above the normal between the axillary and the rectal methods, which Madelung has found to be pathognomonic of suppuration in the lower portion of the abdomen or the pelvis.

L. does not operate during the interval between the attacks, only at the express wish of the patient. He then opens down, releases all the adhesions which seem, to him, to be of pathological origin, and then invaginates the stump into the cœcum. If diffuse peritonitis is present, a section is unavoidable, indeed strictly indicated. If the pus formed has become incapsulated, he tries, if possible, to avoid opening into the free abdominal cavity and prefers to drain, and, with the aid of antiseptics, feels certain that this method is less dangerous than to allow an unopened, undrained pus pocket to remain in the pelvic cavity.

His incisions are usually in the median line or laterally. If the latter, he directs his incision along the motor nerves, in order to avoid hernia. During the operation, the author uses a warm solution of sodium chloride (sometimes 20 to 30 litres). If at all possible, the appendix is removed, and generally no intestinal suture is made, but he closes the opening by the application of Pean's forceps, which are left in the wound; drainage of iodoform gauze is used between the loops of small intestines, Keith's glass drain is also placed. The accumulative fluid is aspirated during the 24 hours, once in 3 hours or oftener if necessary.

Narcosis, at first chlorform by drops and later ether. The after treatment consist in small doses of morphia for the existing pain. To avoid symptoms of ileus, the stomach and intestines are washed out; nourishment is given as early as possible and in rapidly increasing doses. If necessary, warm enamata (500 to 600 dr.) are given to check the thirst, once or twice daily.

The continnance of even slight symptoms of ileus is an indication, to the mind of the author, of more abscesses or of fecal accumulations. As a rational treatment in cases of relapses of perityphlitis, L. recommends careful massage, but only in the Doctor's hand; this may also be the best method by which he will be able to gain thorough knowledge of the anatomical conditions present.—*Centralb. fur Chir.*, 1893.

# ABSTRACTS.

## MEASUREMENTS OF THE LIVER AT DIFFERENT AGES.

Little has been written on the normal measurements of the liver and their pathological variations during infant life.

The clinical measurements are relatively easy to make and to practicing physicians are of more importance than a knowledge of the various diameters and the weights.

These last can never serve as a means of comparison between the conditions of health, of functional derangement and of serious pathological changes. It is not possible clinically to determine the absolute dimensions of the liver, because of its being surrounded by resonant viscera —the lungs and intestines. Clinical measurements are, however, of value if they show a regular progression according to age, their variations depending simply on passing troubles of digestion. The author quotes from Vogel, of Dorpat, and gives the description of clinical examinations which he has adopted.

Physical examination of the liver is made in children exactly as in adults. Percussion in the axillary and mammary lines determines the measurements of the right lobe, and percussion in the vertical line through the sternum that of the left. Restlessness in little children makes this determination difficult. We generally cannot establish the influence of respiration on these measurements before the age of three years. The mammary and axillary lines are the only ones upon which Douchez believes percussion to be of practical use. He has often, in cases of considerable hypertrophy of the liver, failed to find any evidence of increase in its posterior face by means of percussion on a vertical line drawn through the scapula. He believes that there are three causes of error in examination that are of especial hindrance in children. They are excessive resonance of the thorax, resistance of the abdominal muscles, and distension of the stomach and intestines by gas. The greatest source of error is the extreme resonance of the thorax, especially in the newly-born.

In spite of care, measurements on the living are commonly a little less than on the dead. This statement the author proves by a table showing the results of many observations. Nevertheless, although giving less liver dulness than similar examinations after death, these results in the living represent really the impression given to the finger and ear ; and the error, if it be one, is reproduced uniformly and proportionately at all times.

In certain cases, indeed, the demarcation of the upper and lower borders of the liver by percussion may leave doubt in the mind, and it is then well to verify by palpation. When the lower border extends abnormally low, palpation immediately below the false ribs encounters a certain resistance provided the child will relax his muscles. If, on the contary, he holds himself tense, the finger meets with resistance at any rate; and it is well to repeat the observations several times in the same place.

Percussion serves better than palpation to define the slender edge of the liver, which is easily displaced. This thin edge of the liver may be resonant to percussion on account of its thinness and its relations with the intestine; and this occurs even after the abdomen has been opened. The child is best examined on his left side, the arm being raised, the hand grasping the bed and the left flank supported on a pillow. Percussion should be made on both the mammary and axillary lines; the two observations serving as a control upon each other, for the upper line of dulness is practically on the same horizontal plane in both of them.

In order to best show the relation of measurements, the writer has grouped his observations into three classes :

1. Measurements on the cadaver before and after opening the subject.

2. Measurements on the liver of the living in health.

3. Measurements of the liver of the living in disease.

The author presents a table of 88 observations. He finds that in the greater number of infectious diseases, including even measles and diphtheria, it is not uncommon to find enlargement of the liver, due probably to incomplete elimination of

the poison. His conclusions are as follows :

1. The exact determination of the borders of the liver in children is difficult, because of the involuntary contraction of the muscles, also on account of the resonance found over the thin lower edge and of the oblique position of the upper border.

2. The measure of dulness of the anterior face of the liver, in the living, is almost always less by one or two centimeters than the real measure on the cadaver, either before or after opening the abdomen; we should therefore estimate this dulness from its extreme limits in order to reach as nearly as possible to the truth.

3. The upper border of the liver corresponds in general to the interval between the fifth and sixth ribs.

4. In the healthy state, the vertical measurements increase almost regularly with each year's growth, excepting in certain individuals.

5. This appreciable growth between the second and ninth years ceases almost entirely by the twelfth year and can be measured in centimetres by adding one, two or three centimetres, an additional centimetre for every year of the child's life up to eight years exclusive. Beyond eight or nine years the liver dulness measures approximately nearly, but not quite, one centimetre for each year of the child's life.

6. The liver was found *somewhat large* in cases of catarrhal jaundice and gastric disturbance; *large* in cardiac disease, *very large* with amyloid liver, syphilitic liver, fatty liver and hydatid cysts.

7. The slightest disturbance of health may cause a variation of two to four centimeteres, and a variation of three to ten centimetres was found with certain grave lesions.—*Douchez: Revue Mensuelle.*

## ARTIFICIAL DIAMONDS.

Mr. Torald Sollmann, a registered pharmacist of Ohio, for the present residing in Paris for the purpose of the pursuit of special branches of study, writes home to friends a very interesting account of some experiments and demonstrations in the manufacture of artificial diamonds, which we are kindly allowed to reproduce. He says:

"Yesterday I saw the biggest thing here yet. One of the fellows at the laboratory gave me an entry ticket to a lecture on diamonds by Prof. Moisson, of the School of Pharmacy. Several months ago, he first succeeded in making artificial ones, the first real diamonds ever made; former ones all turned out to be quartz. The lecture lasted an hour, and it took place in the big amphitheater of the Arts and Metiers Building. There was not a vacant space in the room, even the stairs were occupied. The lecture was illustrated by experiments which were the most interesting part, something I don't suppose I will ever see again. The professor started out by saying that the diamond and the other forms of carbon were chemically identical. To prove it, he burned some lampblack in a tube through which a current of oxygen was passing, and conducted the carbonic acid into limewater. Then he burned a diamond. It was done in a platinum tube heated by a Bunsen burner, in a current of oxygen, the carbonic acid being also conducted into limewater. The image of the interior of the tube was thrown on a screen, by means of a stereopticon, and we could see the little diamond gradually disappear. Then he further proved the identity of diamond and graphite by placing a diamond in the electric arc, when it was changed into graphite. Then he told us the difference between the various forms of carbon, that it depended upon the molecules combining among themselves. The diamond crystalizes in octohedra, the graphite in hexagons, the other forms are amorphous; the diamond scratches the ruby and can, when in fine powder, be separated from graphite by a liquid of the specific gravity of 2.3, in which the latter floats, whilst the former sinks. This he also illustrated. Then he came back to his subject proper. When he took up the subject of producing the diamond artificially, he started in by studying the earth in which it was naturally formed. He

found that all the earth, wherever found, contained a large amount or iron. Here he exhibited a piece of diamond-bearing clay from the Cape. Then he gave an account of his experiments. He brought a mixture of carbon and iron to an intense heat. Here he described the furnace he employed and showed it. It produces a heat of 3500°C. (6300°F.) It is formed by an electric arc with 400 amperes, inclosed in a furnace of lime, which is the only substance capable of withstanding that temperature. Well, he heated his mixture, and obtained graphite. For two years he kept on experimenting, substituting gold, silver, nickel, manganese, chrome, and everything else, and he invariably obtained graphite. It began to dawn upon him that something else was necessary and that something was pressure. About that time they discovered a meteorite which contained microscopic diamonds, identical with the microscopic ones found in large numbers in all the diamondiferous clay. This put him on the track, for iron possesses the property of contracting in passing from the liquid to the solid shape. In producing this change suddenly, the pressure produced by the solidifying outer envelope on the still liquid inner mass is something enormous, and any carbon inclosed in it will be subjected at the same time to a high degree of pressure and heat. And that is the way he makes his diamonds, which he now proceeded to do, or rather several assistants did it. The iron containing carbon was placed under the arc in the furnace already described and the current turned on. The lime is such a good nonconductor that he could place his hand on it two inches from the place where the temperature was 3500°C. That is the highest temperature possible to obtain with our present means, as then the carbon of the electrodes begins to volatilize. After melting it for a while, the cover was taken from the furnace, the crucible (burned to a white heat, so intense that the operators had to wear blue spectacles), was lifted from it by forceps, and plunged into a jar of cold water. Plunging iron of 6300°F. into cold water is rather a dangerous experiment and enthusiasm ran high. I can't explain the phenomena which took place. It did not make much noise and no spurting, but for a time a good sized flame was over the water. After a minute he took it out again and let it cool gradually. He then performed the same experiment with carbon and silver. After cooling they are treated with hydrochloric and nitric acids respectively, the graphite separated from the diamonds by means of sp. grav. and it is finished. We did not see that part of it, it would have taken too long, but he showed us by the stereopticon, first, the diamonds of the meteorite, then his artificial ones. The largest is 3-10 of a milimeter in diameter. At present it will be impossible to make them 'handsomer and larger,' the conditions of heat and pressure being unrealizable, but at least we can make diamonds. — *The Phar. Era.*

### Scrotal Eczema.

The following is recommended (*Memphis Med. Mo.*):

℞

| | |
|---|---|
| Hydrarg. chlor. mit. | ʒi |
| Zinc oxidi | gr. xl |
| Bismuthi subnit. | ʒiss |
| Lanolin | ʒi |
| Vaseline | ʒss |

M. Ft. ung.

Sig.—Wash the scrotum in hot borax water, and apply the ointment night and morning.

---

### Spice Plaster.

Parrish.

Powdered capsicum,
Powdered cinnamon,
Powdered cloves, of each, 2 ozs.
Rye meal,
Spirits,
Honey, of each, a sufficiency.

To be make into a cataplasm by trituration on a plate, and spreading upon a close fabric. It should be made up extemporaneously when required.

---

### Urticaria.

Sodium salicylate, in doses of three grains every two hours, is said to be very efficacious in relieving urticaria. Three or four doses usually suffice for a cure of the most obstinate case.—*Med. Record.*

---

### Hardening and Coloring Plaster of Paris Casts.

First dry the casts in an oven heated to about the temperature used in baking bread. After they have cooled so that they can be handled without burning the hands, immerse them in a strong, clear solution of alum, and let remain until the alum commences to crystallize on the surface. Remove and wipe off the alum with a wet rag, and again dry in a warm(not hot) oven. When entirely dry immerse in boiled linseed oil cut with a little turpentine. When this is nearly dry apply bronze powder of the desired hue. — *Nat. Drug.*

# CURRENT LITERATURE REVIEWED.

THE MONTREAL MEDICAL JOURNAL

for July. Dr. A. D. Blackader contributes an article on the

**Etiology of Tuberculosis.**

In regard to the influence of heredity, the author states that it is the very rare exception to meet with hereditary tubercle, meaning thereby the congenital transference of the virus, so that the infant enters the world with the bacilli in its tissues. In the vast majority of cases, heredity in tuberculosis signifies only "an excessive hospitality for the tubercle microbe, or a deficient capacity for dealing with him on the part of a too feeble phagocyte."

It may be said, then, that the view generally held at present in regard to the hereditary character of tuberculosis is that cases of true heredity are extremely rare, but that instances may occur where the mother is suffering from general miliary infection, or from definite tuberculous disease of the genital system.

In reference to acquired infection, there are three paths by which the bacilli may obtain entrance: (1) By inhalation through the respiratory tract. (2) With the food through the alimentary tract. (3) By inoculation. Of these perhaps the most important is the first—by the inhalation of dust containing the bacilli in a dried state. These bacilli appear to have great powers of resistance, and are able to retain their infective powers for a long period of time. While in a moist state they do not appear to escape from the sputum, but when the sputum becomes dry it is readily converted into dust, and the bacilli are then liable to be diffused through the air. Great care should therefore be taken over the expectoration of tuberculous patients, that it be thoroughly disinfected as soon as raised and afterwards destroyed, else the apartments occupied by such patients become infective in time through such dust clinging to carpets, bedroom hangings, etc. Not only may the living apartments become infective, but business offices and railway carriages, and even the dust of the road-side become a source of contagion.

The predilection of the apices to the occurrence of symptoms indicative of the presence of the bacilli is well recognized. This predilection has been explained on several theories; among others, it has been referred to an imperfect expansion of the apex or to defective circulation. Recently, it has been pointed out that the thorax at the apex lacks contracting muscular tissue, and with forced expiration there is a recurrent passage of air into the upper lobes, interfering with the expulsion of any foreign substances that may have entered the bronchial tubes. When they have once entered this part of the lung, they experience an amount of rest, which enables them to penetrate to the sub-epithelial tissues and enter the lymph canals. This penetration generally takes place in the alveoli, where the epithelium is non-ciliated, rather than in the ciliated passages of the smaller bronchi.

While, in adults, inhalation of the bacilli and infection through the respiratory tract is much the most frequent origin of tuberculosis, in children the alimentary tract affords an important path through which the bacilli effect an entrance into the system. The upper part of the tract, owing to the very frequent disorders of the throat, mouth and teeth, occasionally becomes the place of primary infection from which the bacilli pass to the cervical and sub-maxilliary glands, and thence may occasion general infection.

Dr. G. E. Armstrong reports

**Five cases of Abdominal Section after Confinement.**

In the first case, fever came on after the patient got up on the tenth day. The symptoms increased in severity till an operation was demanded for relief. At the section the uterus was curetted, swabbed out with a solution of permanganate of potassium and packed with iodoform gauze. The omentum was found adherent to the uterus and left tube and, on separating the adhesions, a pus sac was discovered, which was emptied, the ovary and tube tied off and part of the omentum removed. The patient made a good recovery.

The second case had been attended by a midwife and, at the section, one tube was found enlarged to the size of an adult's wrist and contained small pockets of pus. The ovary was of natural size and gangrenous.

In the third case, the trouble seemed to follow the administration of an enema.

"At 10 o'clock in the evening of the ninth day, the nurse decided that her patient's bowels needed moving. As the baby had a little looseness the nurse though that an enema was the proper thing to give. The patient objected strongly to this, on the ground that after her first confinement she had an enema and that she suffered very great pain for 48 hours afterwards. Her objection, however, was overcome and the enema was given. She was almost immediately seized with intense abdominal pain, with great general tenderness, and vomiting. She had a small stool almost immediately and her bowels did not move afterwards. The vomiting persisted and soon became bilious. Hypodermics of opium were given to relieve the pain. The abdomen became tympanitic, the temperature rose, the pulse became rapid and shabby, the face became drawn and anxious, and it was evident that the patient was suffering from some severe lesion, sufficient to cause a condition of collapse. The history and symptoms pointed to some acute obstruction of the bowels, possibly a volvulus. Her condition was an extremely grave one, and it was easily seen that if anything was to be done more than had already been done, it was of a surgical nature. An exploratory incision was advised.

The peritoneal covering of the intestines was congested and two pints of thin, pale yellow odorless pus flowed out. After thorough irrigation, the uterine appendages and appendix vermiformis were examined without finding any condition that was thought to bear a causitive relation to the peritonitis. The tube and ovaries were tied off. This woman was moribund when the operation was begun and died ten minutes after being removed from the table, or just 24 hours from the giving of the enema and onset of symptoms."

In the fourth case the patient was siezed with severe pain, rigor and high temperature two months after confinement. At the section, a large tubo-ovarian abscess on each side was found, The patient recovered. The author would teach the lesson, from these cases, of strict attention to antiseptic details in confinement and the immediate repair of all lesions occuring in child-bearing.

This number of the magazine concludes with the report of the committee on tuberculosis appointed by the Medico-Chirurgical Society. The following

**Rules for the Prevention of Tuberculosis**

are advised.

1. For the safety of those around him the patient should only expectorate into cuspidors, and when not bedridden he should carry a pocket spit-cup for use whenever in the house and places of public resort where there is no cuspidor available. A simple bedroom cuspidor can be made out of a cup kept for this purpose alone, and half filled with water.

2. To make sure that their contents do not become dried up, and so carried off as dust the cuspidors should contain water. Their contents should be poured daily in the sewer or cesspool (where the bacilli are soon destroyed).

3. Where the patient is up and about, and cannot employ cuspidors, handerchiefs must be used, which are changed frequently, and placed in boiling water so soon as they are done with.

4. The soiled handerchiefs and bed linen of such patients must be kept apart from those of healthy persons, and must be well boiled in the process of washing.

5. Unless the position of the patient render this an impossibility (and in this case, for the safety of the family, he should enter a hospital) the patient must sleep alone—preferably in a room by himself.

6. Whether the patient is up and about, or whether he is confined to bed, the following points should be attended to with regard to the bedroom.

(*a.*) It should be sunny, well ventilated and free from dark corners.

(*b.*) All articles which collect dust should be removed—any carpet present should be replaced by floorcloth. The curtains, if any, should be of light washing material and should be washed frequently in boiling water.

(*c.*) The walls should be whitewashed, or covered by material that can be rubbed by damp bread or damp cloths.

(*d.*) The floor, and the room in general should never be dry dusted, but should be cleaned by damp cloths, so as to prevent the dust flying about.

(*e.*) After the death of a patient suffering from phthisis, the room and bedding should be most thoroughly disinfected. The walls should be given a new coating of whitewash, or may be repapered only after all previous coats of paper have been well dampened and then scraped off. The bedding and clothing of the deceased should be disinfected in the dry steam disinfector; where possible, they should be destroyed.

THE MEDICAL CHRONICLE, OF MANCHESTER, ENGLAND,

for July. The principal article in this month's issue is by T. Arthur Helme, M. D., F. R. S. E., on

**The Relative Position of the Aseptic and Antiseptic Method in Midwifery.**

The author takes the position that reliance on the antiseptic method lulls the practitioner into a false sense of security and the danger is that the principles of cleanliness are lost sight of. It is common, he says, to find that the nurse has given the douche without the least attention to the condition of the nozzle of the syringe, which is often very dirty. Or, the vulva is protected by a napkin which, after lying in a bucket soaked with prutrescent fluids for hours, is gently rinsed off in warm water, dried before the fire and applied. Or, the practitioner uses the douche for the purpose of destroying the germs for which his hands alone are responsible. The author next takes up the bacteriological investigations in regard to the presence of pus-forming germs in the healthy vagina and, after quoting at length the opinions of various observers, unhesitatingly decides that the normal vagina contains nothing which can be detrimental to the patient.

The details of aseptic midwifery are carefully gone into and rules formulated. In regard to the treatment of the patient after delivery, the author says. "The vaginal douche is just as useless and just as harmful, or more so, in a normal case, post-partum as ante-partum; therefore, shun it: and the less said about the intra-uterine douche the better. Indeed, a great deal too much attention is paid to the cleansing of the patient, and a great deal too little to the cleansing of the practitioner and nurse. If only half the nurse's energy were let loose upon her own and the doctor's hands, instead of being devoted exclusively to the squirting of the woman's internal parts, more benefit would result."

He regards the use of the perineal pad as of the greatest importance. It should be made of wool, absorbent, that all discharges may be taken up; sufficiently large, that the outer layers are never saturated. The pad should be composed of antiseptic material. It should be retained by a perineal bandage and changed at least every three to six hours.

The author sums up his paper as follows:

1. The vagina of the healthy normal pregnant, parturient, and puerperal woman must be regarded as *aseptic*. Our object is to prevent inoculation during and after labor: to attain this object, we look to—

(*a*) Thorough cleansing of the hands and arms and instruments, with attention to the clothes and infrequency of examination.

(*b*) Healthy surroundings, pure air, clean sheets, thorough cleansing of the external genitals before and after labor. No internal douching: The use of the perineal pad.

2. The vagina of a woman suffering from chronic discharge is *a priori* to be regarded as septic; our object is to destroy the germs already present, and to prevent fresh inoculation. In addition to the above treatment, therefore, we must here make use of internal antiseptic douching, before, during, and after labor, aiming at sterilization of the vagina.

And among this second group of cases the author would include those to which we are called in emergency, or after they have been for hours, or, may be, for days, in the hands of a midwife, and those where labor has lingered for hours with continuous body discharge or under other doubtful conditions.

With our precautions there will, however, always remain a third series of cases where danger comes from a part not to be reached even by the douche—the tubes—cases difficult of treatment, and still more difficult of diagnosis. But the question of vaginal antisepsis or asepsis does not materially affect these. Puerperal fever will occur, and its cause will probably be discovered post mortem.

The author wishes especially to condemn the unnecessary douching of the normal healthy woman; the faulty manner of douching when the unhealthy conditions necessitate its employment; use of imperfectly cleansed napkins. He would also urge that too much attention is paid to the disinfection of the patient and too little to the disinfection of the doctor and nurse.

Dr. A. Graham Steell contributes a report of "A Case of Aortic Disease with Pulsus Bisferiens," illustrating the report with sphygmographic tracings of the pulse. The remaining paper is a continued report on "Further Cases of Ovarian Cystic Tumors" by Dr. D. Lloyd Roberts.

# PERISCOPE.

## THERAPEUTICS.

### The Use of Cocaine.

1. Amount of cocaine used must be in proportion to extent of surface it is desired to anæsthetize. In no case should the quantity exceed one grain and three-quarters.

2. Cocaine should never be used in cases of heart disease, pulmonary disease, or in persons of highly nervous temperament.

3. In injecting cocaine, the intradermic method is preferable to hypodermic. By injecting into, not under mucous membrane or skin, the risk of entering a blood vessel is avoided.

4. During injection the patient should always be in recumbent position; in operations upon the nose and throat, the head should not be raised until anæsthesia is complete.

5. It is of great importance that cocaine should be pure, since its combinations with certain other alkalies result in poisonous compounds.—*Brooklyn Medical Journal.*

## NEWS AND MISCELLANY.

### Half Rate Excursions to the World's Fair via Washington and the B. & O. R. R.

The Baltimore and Ohio R. R. will run a series of special excursions from New York to the World's Fair at rate of $17.00 for the round trip. The trains will consist of first-class day coaches equipped with labatories and toilet conveniences. The trains will start from Jersey Central Station, foot of Liberty Street, New York, at 8.30 A. M., Aug. 5th, 9th and 15th, and reach Chicago at 4.30 P. M. the following day. Tickets will be valid for outward journey only on the special trains, but will be good returning from Chicago in day coaches on any regular train within 10 days, including day of sale. Stops will be made for meals at the dining stations on the line. A Tourist Agent and a train porter will accompany each train to look after the comfort of passengers. Tickets will also be sold for these trains at the Jersey Central offices in Newark, Elizabeth, Plainfield, Bound Brook and Somerville. New York offices 172, 415 and 1140 Broadway, and Station foot of Liberty Street.

### Picturesque Route to the Fair.

No other line offers the variety of scenic interest between New York and Chicago that is enjoyed by World's Fair tourists via the Baltimore and Ohio Railroad. Passing through Philadelphia, Baltimore, Washington, the capital of the nation, and by way of Harper's Ferry and the historic Potomac Valley to the Allegheny mountains, which are crossed at an elevation of 3,000 feet above the sea, the traveler sees the arena of the activity of the nation as well as the principal historical features and scenic wonders of the East. Low rates.

## ORIGINAL ARTICLES.

### THE USE OF MILK IN HEALTH.*

H. F. SLIFER, North Wales, Pa.

The object of this brief paper is to present a few important data upon which to base the rational administration of cow's milk in health.

Milk is a substance furnished and intended by nature as the sole food for the young of all mammals, and, for a considerable period of their existence, they feed upon it exclusively. It therefore, represents a complete food, in which are present all the elements necessary for the nutrition and growth of the body. The various substances composing milk, and their relative proportions vary within comparatively wide limits, not only in different races and breeds, but the milk of the individual is subject to extensive variation. Some of the causes are: age, period of lactation, nature and amount of food, time of feeding, state of health and the treatment of the animal,—scrupulous care and kindness should ever attend the milk-producing cow.

It is stated on good authority, that a cow, if frightened, will lose a large percentage of her butter fats for twenty-four hours. As showing the influence of the nervous system on the formation of milk, and controlling the relative proportions, also the total amount of solids: two years ago I attended a child in convulsions caused by the ingestion of unhealthy milk. On investigation, I ascertained that the milk had been secured from a cow that during the night had broken her chain and gained access to a barrel of swill, from which she gorged herself. A few days since, I saw a child suffering from indigestion, fever and vomiting produced by the taking of its mother's milk which, later in the day, it refused. In this case, the milk was altered through the influence of emotional excitement brought on by an altercation with her husband on the subject of intemperance.

It is evident that many conditions will influence the character of milk, varying in degree from a slight loss in the percentage of some of its constituents, to a profound chemical change so that it becomes poisonous.

In consulting the different authors, I find a marked discrepancy in the analysis of milk, showing conclusively that it is not uniform in its composition. According to Foster[1] milk contains:—

| | Woman. | Cow. |
|---|---|---|
| Water | 90. | 87. |
| Fats | 2.75 | 4. |
| Sugar | 5. | 4.4 |
| Proteids | 2. | 4. |
| Salts | .25 | .60 |
| | 100.00 | 100.00 |

The fact that human milk is poorer in proteids, fats and salts, is of practical importance when cow's milk is substituted in the feeding of infants. The chemical reaction of human milk is alkaline; cow's milk neutral or acid. Human milk is free from bacteria; cow's milk contains numerous bacteria, when it reaches the con-

*Read before the Montgomery County Medical Society July 26, 1893.

1 Text Book on Physiology.

sumer. Human milk is richer in sugar and water than cow's milk.

In the process of digestion, the casein of human milk coagulates in small flœculi in the stomach and is readily digested, while that of cow's milk forms large and firm coagula which dissolves with difficulty in the gastric juice. In prescribing milk, it behooves to keep constantly before the mind the above facts to assure success in the use of this important agent. I am of the opinion, that, with close study of each case on the part of the physician, and a reasonable amount of intelligence on the part of the mother or nurse, the cow's milk can be so modified as to bear so close a resemblance to human milk, that it becomes applicable in a large majority of cases.

Moreover, it has been conceded by all the higher authorities that animal milk is the proper food for children during the period of growth and development.

Prof. Henoch,[2] of Germany, says: "Cow's milk is but the substitute for mother's milk during the entire period of infancy. I consider the administration of other substances advisable only when good cow's milk cannot be obtained."

J. Lewis Smith,[3] of New York, says: "Milk should be the chief article of food during infancy, after the first year the food may be made of such consistence as to be given with the spoon."

A. Jacobi,[4] of New York, says: "The substitute should be as near normal woman's milk as possible; and naturally, when the latter cannot be had, animal milks are selected."

For the adult body in a state of health, milk is not a typical food. To furnish the required amount of carbo-hydrates, to supply potential energy for moderate labor, twenty pints would be required, which would give an excess of fats and proteids; so large a quantity of fluid would interfere with the digestive function, and soon overtax the kidneys.

The food for adults, therefore, must be more concentrated, and richer in the carbohydrates.

The most important use of milk in health, is in the feeding of infants and children. During this period, when the circulation and metabolism is most active, the tissues containing an excess of water, milk is peculiarly adapted for the nutrition of the body.

To be successful in the use of milk, the following condition must be observed:

1, The quality of milk used.
2, " quantity of milk used.
3, " time of feeding.
4, " manner of feeding.
5, " proper dilution.
6, " " addition.
7, " predigestion.

Milk should be as fresh as possible, and preserved upon ice. If this is impracticable, it should be sterilized and bottled and kept cool. If milk free from impurities and perfectly fresh can be procured twice daily, it is not always essential that it should be sterilized. Milk should have a sweetish taste. Neutral or but faintly acid in reaction. Sp. Gr. 1029. Should contain not less than 3 per cent., nor more than 4½ per cent of fats. The proteids, consisting of albunium and casein, should constitute about 4 per cent. The salts, consisting of phosphate of calcium, potassium and magnesium, potassium chloride with traces of iron and other substances, must also exist in a fair percentage. The fats and proteids are more subject to variations than other constituents of milk; therefore, demanding the most careful attention.

In regard to the quantity of milk given at each feeding, much care should be exercised. I am convinced that more children are over fed, than underfed. We should ever remember the capacity of the little stomachs, designed to receive and digest the milk.

According to the measurments of Dr. T. M. Rotch,[5] of Bostom, "The capacity of an infants stomach 5 days old is 25 cubic centimeters, (7½ drachms). Two months, 120 C. C (4 ounces). Twelve months, 300 C. C. (10 ounces). Two years, 740 C. C. (25 ounces). In regulating the amount of milk, a fixed rule cannot be adhered to in all cases, since individuals differ in their capacity and physiological demands. I am guided somewhat by the following index:

| Age. | Intervals. | Amount. |
|---|---|---|
| 1 Month | Every 2 hours during the day. | 1 oz. |
| 2 Months | | 2 " |
| 3 " | | 3 " |
| 4 " | Every 2½ hours during the day. | 4 " |
| 5 " | | 5 " |
| 6 " | | 6 " |
| 7 " | Every 3 hours during the day. | 6 " to 8 " |
| 8 " | | |
| 9 " | | |
| 10 " | | |
| 11 " | | |
| 12 " | | |

2 Lecture on Diseases of Children.

3 Diseases of Children.

4 Intestinal Diseases of Children.

5 Cyclopædia of Diseases of children, Keating.

I feed as little as possible between the hours of 9 P. M. and 5 A. M., thus to enable the child and attendant ample time for sleep. Some children can do with one feeding, others demand food two or three times during the night. As the child advances in age, I decrease the night feedings, and prolong the hours of sleep.

The manner of feeding resolves itself into the simplest possible mode. Infants under twelve months of age, should feed exclusively from the bottle. In selecting the fittings, avoid all ostentation; I prefer a plain bottle with a short neck, with the proper capacity adapted to the age of the child, a plain rubber nipple with a small aperture. The child while nursing should repose in a comfortable position, and attended by a person who will remove the bottle as soon as the supply of milk is exhausted. Under no conditions, should the child be permitted to suck or play with the empty bottle. It should immediately be cleaned and placed in water, or water with the addition of soda or borax, until the next feeding. Milk should always be given at a uniform temperature, approaching that of the normal temperature of the stomach, about 100° F.

In substituting cow's milk for human milk, it is important to modify the former, so as to more closely resemble the latter. In comparing the analyses of the two, we observe that the cow's milk is richer in proteids, fats and salts. Very naturally, we endeavor to reduce these elements to their proper percentage; this is accomplished by the addition of water, which reduces all the constituents in an equal proportion, even those that are already deficient; this necessitates the addition of such constituents. The water employed for dilution, should always be boiled to destroy all organic substances which it may contain.

Water not only acts as a diluent, but alters the physical condition of the casein so as to render it more digestable, by preventing the formation of large coagula during peptogenic digestion.

The degree of dilution neccessarily depends upon the composition of the milk, the age and condition of the child. The following is my rule for dilution:

| | | | | | | | | | |
|---|---|---|---|---|---|---|---|---|---|
| Age | 1 | Month | 1 | Part of | Milk to | 3 | Parts of | Water. |
| " | 2 | months | 1 | " | " | 2 | " | " |
| " | 3 | " | 2 | " | " | 2 | " | " |
| " | 6 | " | 3 | " | " | 2 | " | " |
| " | 9 | " | 3 | " | " | 1 | " | " |
| " | 12 | " | 6 | " | " | 1 | " | " |

In case of indigestion, which is frequently due to an inordinate amount of proteids or fats, my experience has taught me that by increased dilution, and a reduction in the quantity of each feeding, the child is soon restored to its normal condition. There are also cases in which the fats are poorly digested and cause fatty diarrhœa; under such conditions, a portion of the fats should be removed and the usual quantity of water added.

Milk that has been properly diluted requires the addition of such elements as are deficient. Sugar should be added to the amount of two drachms to the pint. The kind of sugar which should be used is unimportant. It is natural to suppose that milk-sugar should be prefered, since it is a normal constituent of milk. Cane sugar, however, is less liable to undergo fermentation and is more readily digested. If a good quality of milk is used, it is seldom necessary to add cream; yet, in cases of constipation I have found the addition of cream to be beneficial. Owing to cow's milk being more or less acid, the addition of an alkali is essential; bicarbonate of soda or lime water will meet this indication. If constipation exists, phosphate of soda or magnesia should be used. Authors frequently speak of additions of farinaceous substances. My experience with these agents has been unsatisfactory. They are useful only so far as their mechanical action on the milk and irritating influence on the bowels are desirable. They are objectionable for two reasons: 1st, they differ too materially from normal milk elements; 2nd, they are difficult to digest. During early childhood the peptogenic functions predominate; the diastatic functions are not fully developed until later in life; and not until these two functions are equally balanced do we find vegetable matter properly digested. These substances undergo a more radical chemical change during digestion than animal substances. Since the peristalis in children is more active and the bowel comparatively short—according to Treves: "the length of the small intestine at birth is nine feet, and the colon one foot,"—the food does not remain sufficient time in the bowels for perfect solution and absorption of vegetable substances.

In children of naturally feeble digestion it is necessary not only to modify the milk

by dilution and additions, but to predigest it to a degree that the most delicate stomach will retain and digest it. This is accomplished by the use of a digestion ferment, either pepsin or extract pancreatis. So far as my experience goes, I prefer the pancreatis, its peptoinizing action is more energetic and capable of digesting every form of food. The casein is so altered as to resemble human milk and is regarded by Dr. Albert R. Leeds as humanized milk.

In conclusion, as soon as the profession recognizes the importance of this subject, and exercise the same care in the selection and administration of milk that we exercise in the selection and administration of drugs; and more fully appreciate the appeal that is made to us year after year by that gigantic infant mortality, so soon will we reach a consummation most desirable.

# CLINICAL LECTURES.

## NASAL DEVIATIONS.

DR. GEORGE M. LEFFERTS.*

GENTLEMEN :—Nasal deviations may be divided into three great classes, viz: (1) Those due to severe crushing injuries, such as the kick of a horse, which belong to general surgery; (2) angular, curved, and sigmoid deviations; and (3) outgrowths from the nasal septum.

Setting aside the extreme cases of crushing injury of the nose, we come to a class of cases in which the injury may have occurred within the memory of the patient, but more frequently has happened so long ago that he does not recollect it at all. Rest assured, however, that somewhere in life-time of that patient if he have a nasal deviation, there has been an injury to the nasal septum. Probably when he was but a very little child, he has fallen, and the injury has been done at this time, and has not attracted any attention.

The septum should be a perfectly straight, thin, cartilaginous partition between the two nasal passages. The first form of injury to which I shall ask your attention is *angular deviation.*

On one side, you will notice a cartilaginous and bony projection, reaching well out into one nasal passage, and in the other nasal passage, there will be a concavity. The next form is known as *curved deviation.* In this, the bony septum is bowed out into a large curve, which is thin and quite resilent. Here, again, in the one passage there is a projection, and in the other, a corresponding concavity. The third or *sigmoid deviation,* is rather more difficult to diagnosticate. This diviation always involves both the cartilaginous and bony portions of the nasal septum.

These are the three forms which are commonly seen, and which are the only ones you need remember. In almost every case, these deviations have been produced by some injury at a remote period. All three forms give rise to nasal stenosis. The first result of a blow on the nose in childhood will be chronic hypertrophic rhinitis, a condition which requires years for its development. The deviated septum and the hypertrophic rhinitis together produce a severe stenosis, and as a result of this obstruction, the patient is deprived of the sense of smell, his voice is harsh and muffled, and his hearing is defective. This last condition is due to the fact that the chronic catarrhal process has extended through the Eustachian tubes, or, as a result of the constant rarification of the air in the middle ear, the external pressure constantly drives the drum inward, and this, with the chronic resulting hyperæmia, makes the patient more or less deaf. Secretions lodge upon the irregularities of the nasal passages; they are removed by the patient, and an abrasion or ulcer is the result; and is very commonly associated with recurrent epistaxis. In such cases, always look on the side of the nasal

*Professor of diseases of the throat and nose, College of Physicians and Surgeons, New York.

septum near the front, and you will often be rewarded by finding the origin of the bleeding. Let me repeat—as a result of the nasal deviation, there will be mouth-breathing, chronic pharyngitis, chronic laryngitis, occlusion of the nasal passages, loss of resonance of voice, epistaxis, and dry, inpacted secretions.

The sigmoid deviation is a comparatively rare form requiring special operative skill, and often a multiplicity of instruments for its proper relief; so, in order not to unduly complicate this subject, I shall exclude this from consideration, and shall ask your attention only to two common forms of nasal deviation—the angular and the curved.

With the Adams forceps, the nasal septum is grasped firmly, and twisted into place, and maintained in this new position by means of intra-nasal plugs during the healing process. It is a most uncomfortable treatment, and the results are most unsatisfactory. Another method of operating is with the stellate forceps, an instrument which makes a stellate incision through the curved deviation. This enables you to place the septum in the median line with much less force, and then the after-treatment is carried out with the intra-nasal plugs as before. The operation is theoretically very good, but the treatment is very annoying, and the results do not seem to me to justify its use.

Another operation consists in using a forceps which will punch out several pieces from the nasal septum in the portion of greatest convexity. You may undoubtedly by this means clear the nasal passages, but you have left a communication between the nasal passages, a condition which is almost certain to prove uncomfortable to the patient all his life time. A simpler, much more comfortable, and effective operation consists in introducing a long brass pin through the curve in such a way as to hold it approximately in the proper position. This process may be facilitated by making two or three slight incisions into the septum. This pin can be worn without great inconvenience to the patient until the septum no longer tends to return to its former abnormal position. This is the best method of treating curved deviation.

An angular deviation is best treated by sawing off or cutting off the obstruction under cocaine anæsthesia. In doing this, you must be careful not to make an opening into the adjoining nasal passage.

We must next consider out growths from the nasal septum—exostoses or enchondromata, if you please, There has been a blow on the nose which has most often driven the cartilaginous septum against the articulation of the vomer with the maxilla. This has resulted in a very slow perichondritis, and the slow formation of a cartilaginous or osseous tumor. The differential diagnosis is made from angular deviation by observing that there is no corresponding concavity in the other nasal passage. Hypertrophic nasal catarrh will occur in every case where there is a deviation or projection of the nasal septum. In this third class is to be found the most frequent causes of nasal occlusion, and also the simplest method of removing the obstruction. The operation is performed either with a nasal saw, or with the nasal trephine, driven by an electric motor.

### A Taste for Science.

Little Dick—"I know how to tell how deep a well is without going down."

Father—"Ah, I'm glad to see my son has a taste for science. You drop in a stone and count the number of seconds required for the descent, I presume?"

Little Dick—"Oh, no, I tie the stone to a string and then measure the string."—*Good News.*

### Otalgia.

*Le Progres Medicale* recommends the following in otalgia:

℞
Camphorated chloral..... 5 parts.
Glycerine.....30 "
Oil of sweet almonds.....10 "

Dip a tuft of cotton into this and introduce it into the patient's ear.

### For Migrane.

The following is recommended:

℞
Butyl-chloral hydrat.....grs. xv.
Tinct. cannabis indicæ.....mxv.
Tinct. gelsemii.....mxxx.
Glycerin.....f℥iv.
Aquæ.....ad f℥iij.

Mix. Sig.—An ounce to be taken at once; to be repeated in half an hour.

If a Child Die in the Uterus, Prof. Parvin says, the mother will not manifest any unfavorable symptoms unless air enters the uterus, in which case putrefaction will take place with all its unfavorable symptoms, particularly diarrhœa and chills.

# COMMUNICATIONS.

## THE EARLY REMOVAL OF TUBERCULAR FOCI OF BONE.*

B. MERILL RICKETS, M. D., Cincinnati, Ohio.

It is not my intention to address you at any very great length, or present to you a subject upon which no thought has been given by the surgeons in general. My intention is to present some evidence that may lead us to make an earlier diagnosis and to adopt more prompt and radical measures in tuberculosis of the bones than are generally adopted. Tuberculosis is one of the greatest enemies which the human body encounters. It is surely the greatest destroyer of its bony anatomy. When once the frame, or any part thereof becomes diseased, the interest of all that is dependent upon it, becomes jeopardized. Syphilis has been accredited as the great destroyer of not only one, but of all kinds of tissue. It is a blessing compared to the ravages which tuberculosis produces, for in syphilis we have a remedy without much surgical interference. In tuberculosis, our hands seem to have been tied, and the wheel of progress in its treatment been made to stand still. There seems to be no constitutional treatment whatever of the least benefit in tubercular disease of the bones. It is not because there has been no effort, for medical literature has been flooded with the various remedies suggested for its cure. It seems now that tuberculin has fallen short of our expectations, failing in every particular, and giving no good results whatever. To my mind, the good to be obtained is through surgical interference only, and it then depends upon early operative procedures. Aseptic surgery has been the greatest boon to this class of work, and we must necessarily rely to a great degree upon cleanliness. However, we see how difficult it is to secure primary union even in the extirpation of tubercular glands. Seeing how hard it is to overcome these obstacles and to secure primary union in operation upon the soft tissue, we must necessarily shrug our shoulders when we come to the extirpation of tubercular disease of the bones and joints. However much I might be gratified to present this subject to you voluminously, I must confine myself to the early extirpation of the tubercular foci in the bones. I believe that surgeons in general are responsible for a large per cent. of the cripples as the result of tubercular disease, and I am thoroughly satisfied that there has been too much delay, and that we have expected nature to do what we ourselves should have done. My own plan has been to act promptly and radically where I have evipence of tubercular disease of either the shaft or epiphysis. Even where there is a question as to the identity, it is best to give the patient the benefit of a doubt and operate promptly. In nearly all of the cases where the periosteum is thickened and tender, we have reason to suspect the presence of tuberculosis. Even in cases of trauma, tubercular bacilli seem to find their way and develop rapidly in the injured tissue. When once they are implanted, they are not long in manifesting themselves and giving evidence of their presence; therefore, it is in just such cases as these, especially of the long bones, that an exploratory incision and early extirpation give such excellent results. It is a matter of course that one should hesitate to open a joint as promptly as he would a shaft, but unfortunately the shafts are not so frequently attacked as the epiphyses. It is a great question, and one which must be considered greatly from the light of experience, as to the time when a joint should be opened; however, I am safe in saying that the disease should be removed earlier when it attacks the epiphysis than when the shaft alone is involved. If the foci are thoroughly removed, let them be upon the surface or in the body of the epiphysis, then the destruction of bone is much less and its ability to repair itself much greater. Then too, when early extirpated, the possibility of the other bones being involved is lessened; the disease, when confined to *one foci*, is not so rapid in its progress as where several are to be found, although the single one

*Read Before Mitchell Dist. Med. Association, Baden Springs, Ind.

may be as large as several of the smaller ones combined. Then too, the greatest number of tubercular foci are found in the epiphysis because of its spongy nature. There is not so much liklihood of the foci being multiple in the shafts, because they are more compact.

I do not believe that there is one foci in a thousand that undergoes spontaneous recovery, let it be in the shaft or epiphysis; much less is it likely to recover when found in the epiphysis. Even rest, which has been so long considered a cure for tubercular joints, is of but little avail, giving to my mind, no evidence whatever of the reparative process as the result. When once an area has become attacked by the bacilli, there seems to be no limit to the destruction which it may produce. If they do not become multiple, the one will in the course of time destroy all the adjacent tissues. Tuberculosis of the epiphysis is what epithelioma is to the skin, and should be looked upon with as great consideration, and the treatment made as radical. The earlier an epithelioma is removed, the greater the chances for a permanent relief. Just so with a tuberculous area within the bone. The influence of the diseased area seems to be nothing more than that of a foreign body, except that the disease is more rapid and progressive. The opening of a joint free from any disease could result in nothing more than a certain amount of ankylosis. A joint affected with tuberculosis, necessarily results in ankylosis to a greater or less degree. Now, is it not better in cases where there is every indication of tubercular deposit, to give the patient the benefit of a doubt in exploratory incisions, followed, if necessary, by the removal of tuberculous matter? Until recently it was almost a crime to open the abdominal cavity. Now it has become quite a common occurrence, even though doubt exists as to what is to be found within that cavity. Just so with tuberculosis of shafts, and especially joints. What can we expect from any other than radical treatment? The development of large ovarian tumors does not now occur, simply because the gynecologists have become so skilled in making early diagnoses that procrastination can no longer be attributed to them. It is to be hoped that surgeons who are called upon to treat the various forms of tuberculosis, especially of joints, will not delay radical operative procedures until there is great derstruction of bone, accompanied by the formation of fistulæ. This is deplorable, and I think is largely due to the surgeon himself. Perhaps he does not early recognize the disease, or it may be due to his inclination to procrastinate, or his fear in assuming responsibility, but it is as unscientific to allow the head of the femur to become destroyed from tuberculosis, as it is to allow an ovarian tumor to grow until it weighs 50 or 75 pounds. It is one thing for the patient or other influences to be responsible for such a state of affairs, and it is another for the responsibility to rest upon the attending physician. Just how much of the adjacent bone should be removed with tubercular foci, is a question for the operator himself to decide. I have no doubt but that, in the majority of hip-joint cases, the disease has progressed to a greater degree than is generally supposed at the time it is presented for treatment. We must expect all degrees of progress in the destruction of bony tissue as long as the people are isolated and out of reach of surgical aid. Poverty and indifference are prominent factors in the delay of treating all classes of disease, but this should not be of any influence in establishing laws. Let the rules be established, and the good results made known, and there can be no plausible reason why the application should not become general.

---

A paste which will stick anything is said by Professor Winchell to be made as follows: Take two ounces of clear gum arabic, one and one-half ounces of fine starch, and half an ounce of white sugar. Dissolve the gum arabic in as much water as the laundress would use for the quantity of starch indicated. Mix the starch and sugar with the mucilage. Then cook the mixture in a vessel suspended in boiling water, until the starch becomes clear. The cement should be as thick as tar, and kept so. It can be kept from spoiling by the addition of camphor, or a little oil of cloves.—*Pacific Med. Journal.*

---

Freckles can be removed, according to Hager, by the application every other day, of an ointment composed of white precipitate and sub-nitrate of bismuth, each ʒi; glycerine ointment ʒss.

# FRACTURE OF THE SKULL, WITH PROTRUSION OF BRAIN SUBSTANCE AND REMOVAL OF SAME.*

W. R. GOOGE, M.D., Abbeville, Ga.

It is only recently that intrusion on the brain and membranes has been attended by so small a morality; but, owing to the great success and progress which has been achieved in antiseptic surgery, it is now of common occurrence.

It is not the purpose of this paper to let new light into the subject of brain surgery, but simply to corroborate the fact that if thorough cleanliness and strict astiseptic precautions are strenuously observed, the time will come and to a certain extent now is, that the surgeon may penetrate the most secluded recesses of the human mechanism and perform wonders which were not long ago shrouded in obscurity.

The time has been, and not long ago, when the idea was prevalent that intrusion on the brain or membranes was attended by almost certain death, or to penetrate the abdominal walls and peritoneum was considered folly of the most aggravated type, but thanks to the promulgators of antisepsis, we can now with impunity perform operations of this nature with a very low per cent. of mortality, which none dare to dispute. It is a boon to humanity and should be a source of self-congratulation on the part of every physician.

Fracture of the cranium with protrusion of brain substance and removal of the same, with recovery, is now regarded among the laity and also among some of the practitioners of medicine, as an impossibility, and it is the intention of the writer to disclose the results of a case of this discription and to show, if any doubt exists, that recovery in such instances is of very common occurrence.

On December 18th of last year, Mr. A. B. Pemberton, while guarding convicts for the Ocmulgee Brick Co., at Abbeville, Ga., was struck with the eye of a common club axe, on the posterior portion of the skull near the articulation of the occipital and parietal bones, the blow resulting in a complete fracture with the bone depressed and resting in the brain substance. The depressed bone had loosened quite a quantity of the brain, which, after observing the usual antiseptic precautions, I very carefully removed. It weighed just a little over half an ounce. After carefully removing every particle of matter that could possibly be foreign, I raised the skull with a common elevator to its proper position and placed it in apposition, after which I dressed the wound with iodoform gauze, packing the wound in order to prevent its healing externally; after which he was carried home and put to bed. Strange to say, he could walk and talk sensibly, still he had no recollection of the matter afterwards.

December 19th. Temperature 100° F. Absence of sensation, not being able to feel the prick of a pin; mind wandering. Gave sulphate of quinine and ordered an enema warm soap-suds and water every day.

December 20th. Temperature 101° F. Slight sensation; able to talk but would lose the subject.

December 21st. Temperature 100° F. Sensation returning and complaining of pain in left arm. Wound was right side of head.

December 22d. Temperature 90½° F. Pain more severe on left side. Sensation almost restored. Gave hypodermic of morphia and atropine.

December 23d. Pain gone. Sensation restored, and appetite good. Had eaten nothing since injured, being very much nauseated all the time.

December 25th. Temperature normal. Dressed wound and, strange to say, found no pus whatever. Patient able to sit up for dressing wound.

December 27th. Patient walked up town a distance of one-quarter of a mile, contrary to my directions.

January 1st. Bone had healed and removed packing from wound.

January 5th. Wound granulating nicely.

January 10th. Discharged patient with the wound almost well.

January 28th. Patient thoroughly well and accepted a position on S. F. & W. R. R. as section master.

*Read before the Georgia State Medical Association, April 19, 1893.

The question might naturally arise, are you sure that you removed the brain substance? And in reply I would say, that I never was surer of anything in my life, and can corroborate every assertion by my associate, Dr. A. R. Royal.

## PERIPROCTITIS WITH AN ABSCESS AND REPORT OF A CASE.*

M. L. CURRIE, M. D., Mt. Vernon, Ga.

Periproctitis is one of those infrequent inflammatory diseases which the general practitioner may at any time be called to treat, and which he may fail to recognize until much damage to his patient ensues. If properly diagnosed, it may then be improperly treated, owing to the fact that he cannot always find such a precedent as he needs.

It is usually suppurative in character, but a cure may be effected by absorption, even after a distinct tumor is formed. Of the causes of this disease but little can be said. It may result from traumatism, foreign bodies, extension of adjacent inflammatory processes, or any structural disease involving the mucous membrane of the rectum. The manner of its extension and the course of the morbid processes excited, are identical with those seen in perityphlitis following typhlitis.

The prognosis depends much upon the time when the case is diagnosed, the treatment of both the inflammation and the abscess as well as the physical condition of the patient. When the vitality is low, and the abscess high up in the pelvic cavity, or when the patient is tuberculous it is unfavorable; when otherwise, we may hope for recovery. The diagnostic symptoms and the treatment I will give in connection with the following case.

Case I. Mr. G. B. A., aged 37, weight 200 lbs., very muscular and stout. On the 26th of January last he applied to me for treatment, stating that he had "piles;" that he was going to visit a sick relative in North Georgia, and would be gone two weeks; presuming that he knew his trouble, and without any examination, I gave him the usual prescription to regulate the bowels and an ointment for the hemorrhoids.

On the 18th day of February, I was called and found my patient in bed with a temperature of 102°, suffering with intense pain in and around the rectum; with tenderness of the whole pelvic region. On inquiry he gave me the following history:

On the 6th day of January last, while in the act of defecating, a severe pain was felt low down in the pelvic cavity on the left side, which continued daily, and which was always worse when bowels moved or during exercise. During his entire visit the pain was incessant. The medicine prescribed by me failed to relieve him, and, while riding on the cars, he was unable to sit erect, owing to the pain it caused him. Having carefully examined him, I found some induration of tissue and slight swelling, with heat and much tenderness, below Poupart's ligament on the left side. The sphincter muscles appeared to be spasmodically contracted and the tenderness around the anus was so great that I could not by the use of a 4 per cent. solution of cocaine introduce my finger into the rectum.

For this condition I advised rest in bed, and gave for the pain, morphine and atrophia hypodermically; for the fever, phenacetine and quinine; for the bowels, solution of sulphate magnesia with aromatic syrup of rheubarb and enemata of warm water; for the tumor, I applied warm fomentations.

February 19th and 20th the swelling in left side gradually increased until a tumor as large as a walnut could be distinctly outlined, for which I applied warm starch poultices every two hours. On the morning of February 21st, I discovered that the tumor had greatly diminished. In the evening, with the assistance of Drs. McCrimmon and Summerlin, I made a careful examination, under an anæsthetic, both digitally and through a rectal speculum and could discover no signs of a tumor or abscess except the inflammation. During the next three days, the inflamma-

*Read before the Georgia State Medical Association, 1893.

tion increased, the pain became more severe, attended with constitutional depression and inability to urinate.

February 25th, assisted by Drs. Rogers and Summerlin, I again anæsthetized the patient, and with difficulty I felt the lower edge of a fluctuating tumor protruding into the bowel at the apex of the ischio-rectal fossa, which probably pressed upon the urethra and rendered it necessary for me to use the catheter to empty the bladder.

With the index finger of my left hand resting against the edge of the tumor through the rectum, I passed a medium sized trochar parallel with the bowel straight up for four inches. The opening was then enlarged with a long bistoury and a pair of dressing forceps. Almost a half pint of foul looking pus escaped, having the odor of fæcal matter. The abscess cavity was then cleaned out, and iodoform gauze introduced and the part dressed with absorbent cotton. From the time the operation was performed the abscess discharged freely until the 28th, at which time the gauze came out and with difficulty more was introduced, owing to resistance on the part of the patient. During this time the patient was restricted to fluid diet and a tonic of iron and arsenic with quinine administered. On March the 4th, I introduced a small rubber tube in place of the gauze, which was necessitated by the healing of the wound.

On March 8th, the discharge had about ceased, and the opening to the abscess closed. The patient was suffering with pain, attended with fever and the presence of former symptoms, which increased until the 10th. At this time, assisted by Drs. Rogers and McLeod, I reopened the abscess, with my finger removed all septa of broken down tissue, and washed out the entire abscess cavity with an antiseptic solution of carbolic acid. A soft rubber drainage tube was introduced and the parts dressed as before.

The abscess discharged freely and patient slowly convalesced, but on March 14th, it was discovered that the water injected into the rectum partly passed out at the tube through the abscess.

At this stage of the case my judgment was severely tried to decide whether to subject my patient, who was at this time very weak, the fourth time to the depressing effects of an anæsthetic and sever such important structures as existed between the two openings, or wait for the abscess to heal and then operate for the fistula.

At the suggestion of an experienced surgeon, I waited, and to my pleasant surprise my patient is now able to be with me in this city and is well of both abscess and fistula without an operation.

I report this case hoping that, by so doing, I may be the means of relieving suffering humanity in similar cases through the agency of some one or more of my professional brethren. I believe it would have been better surgery for me to have opened the abscess through the rectum and I know it would have been better when I first opened the abscess to have made the incision larger and removed all septa of broken down tissue.

## HEADACHE VERSUS GLAUCOMA.*

W. L. BULLARD, M. D., Columbus, Georgia.

"These medical sciences stand at a stay, and have done for years," so said Lord Bacon in the sixteenth century. But, could he step forward to-day and look over the literature that has been produced and brought forward relative to my theme, I am quite sanguine that this rare philosopher would change his assertion, partly at least to say that medical science is still a little slow in finding any one remedy as a certain relief for all kinds of headache, but it has reached the highest pinnacle of fame as to cause. The wise men tell us of an anemic, an hyperemic, or congestive, a nervous or cerebral, the toxic, and the bilious or sick headache, all of which have an abundance of causes. The oculists say that most cases

*Read before Georgia State Medical Association, April 21, 1893.

are caused from eye strain, but the gynecologist goes the eye specialist one better, and swears that nearly every case is reflected from uterine or ovarian irritation, while not a few cases are doubtless caused from urethral contraction, and syphilitic lesion of the brain or nervous system, so says the genito-urinary surgeon, and the general practitioner knows full well that nine cases out of ten are caused from a torpid liver or a gastro-duodenal catarrh. Now, gentlemen, ignoring every form of which we have spoken, including the headache the most of us will have the morning following the banquet, I will proceed to tell you of the kind of headache I wish to call your attention to, which is a headache, or possibly more often called neuralgia, a pain caused from and a symptom of a most serious disease of the eye—glaucoma. We have the acute and chronic; in the acute the eye ball becomes red and very much inflamed, with a hard tension of the ball as to touch, a dilated pupil, deep anterior chamber, and a cloudy condition of the aqueous humor and vitreous body accompanied with nausea and vomiting, at times pronounced as a bilious attack. A patient with this kind of headache or neuralgia, suffers at times with the most intense pain extending into the eye from the brow on the nasal side with an œdematous condition of the lid. In the chronic form, it sometimes runs its whole course without causing any excessive degree of redness or inflammatory condition of the ball, and the vitreous and aqueous humors are transparent, rendering necessary an ophthalmoscopic examination with which the pathognomonic excavation of the optic nerve may be readily seen; yet the patient at times suffers intense supra-orbital pain. The storm after a day or so may pass off, but is sure to return at shorter or longer intervals, and the intra-occular tension slowly, but surely, does its destructive work upon the optic nerve fibres until the "windows of the soul" are forever closed. In true supra-orbital neuralgia or, as it is designated by the laity, "sun pain," the suffering is quite severe, the ball red and the supra-orbital notch very sensitive to the touch, but the pain is paroxysmal, beginning in the morning after sunrise, increasing for a few hours, and gradually subsiding in the afternoon before sunset, to begin the next morning possibly a little later than it did on the preceding day. You will find the vision not impaired, the cornea clear, the pupil normal in size and readily responding to the influence of light, which is not the case in the glaucomatous form of headache, and under the treatment of antipyrine, quinine and arsenic the paroxysm is soon checked or broken. While there is some similarity between the two diseases, the differential diagnosis is easily established, yet I am afraid that most physicians have no idea how many human beings are to-day from a mistaken diagnosis, groping their way with vision irretrievably lost, and the victim left as in Milton's soliloquy.

I only wish that I was able to protray to your minds the true realities of which I speak. In an effort to do so, allow me to quote from a lecture delivered at the Chicago Policlinic by that eminent Chicago oculist, Dr. F. C. Hotz: "Gentlemen, it is the fact that the severe neuralgic pain, and the violent gastric disturbances, induced by acute glaucoma, have been taken and treated for "rheumatic or malarial" neuralgia, while the ocular disease has not been recognized until too late. I have seen several cases of this mistake; one was an especially sad case which impressed me so much that I shall never be able to efface its picture from my memory. Though fifteen years have gone by since I have seen the unfortunate patient, her image is before me now as vivid and distinct as if I had seen her yesterday. Two months before I saw her she had been seized with fever, nausea, frequent vomiting, and violent pain extending over the entire left side of the head. Her physician pronounced her trouble to be gastritis, and "sick headache," and when the old lady called his attention to the fact that her sight was getting poorer every day (and she could see with her left eye only; for the sight of the right eye had been destroyed by glaucoma ten years) he assured her she need not worry about it; that her sight would return as soon as the stomach trouble was cured, and the neuralgia in the head relieved. Having implicit confidence in her physician she believed his word, and though her sight soon had vanished completely, she waited hopefully for the day when the darkness would be lifted again from her eyes, and patiently endured the constant, most violent headache, which

robbed her of rest and sleep by day and night. For two weary months this poor woman suffered, and hoped; but then her patience was exhausted and much against the will of her physician she went to consult an oculist. Poor woman! it was too late. The continued high tension of glaucoma had done its deadly work upon the optic nerve too truly, and although the iridectomy effectually reduced the intra-ocular tension, and promptly relieved the patient of the terrible headache so that after the operation she could enjoy a good quiet sleep for the first time in eight weeks, the woman has never seen a ray of light since the awful result of a mistaken diagnosis." Now, gentlemen, I venture the assertion that there is not an oculist of any experience, so to speak, who has not seen cases similar to the one just quoted, and I will quote from a letter bearing on this subject received since I commenced to write this paper. It is by Mr. J. M. Floyd, of Fayetteville, Ala., who says that: "I write you concerning my wife, who has been blind for two years. She is fifty-seven years old; in very good health. About three years ago she was taken with neuralgia in the head, which settled in her eyes; the misery was very intense for some months, after which she became nearly blind. She lost all sight about six months afterward. I took her to an oculist who pronounced it glaucoma, and told her that he could do her no good." Now, I don't know the cause of the delay in this case but am sanguine to say that had there not been a mistaken diagnosis the delay would not have happened, and to-day there would have been one less blind person groping about in the long dark night. May I ask why this mistaken diagnosis? Is it from the fact that we become careless in making our examination, and take too much for granted in what our patient tells us? In truth sometimes do we let the patient make the diagnosis? But who is responsible? The diagnosis is correctly made, the only remedy is the surgeons knife, and the sooner the iridectomy is done the greater the chances for the restoration of vision. No known medical treatment, including Dr. Hammond's cerebrine and medulline, can permanently stay the disease. Physostigma and pilocarpine will check the destructive ravages for a time, giving the afflicted some chance until the surgeon can be seen. Preparations of belladonna, and erythroxylon cocoa which includes cocaine, should never under any circumstances be used in glaucomatous headache, and permanent good need not be expected from any treatment save an iridectomy, as advised by Dr. Græfe some years ago, and which I must add, is one of the grandest triumphs of modern surgery.

## SOCIETY REPORTS.

### STATED MEETING OF THE CLINICAL SOCIETY OF LOUISVILLE.

*Meeting, April 18th, 1893.*

Dr. John G. Cecil, President, pro. tem. in the Chair.

#### TWISTED UMBILICAL CORD, CAUSING DEATH OF FŒTUS AT SEVENTH MONTH.

Dr. P. Gunterman: I have a specimen here which is very small and seemingly very insignificant; still it caused the death of a baby. A woman came to my office about two months ago, who was then seven months advanced in pregnancy. The day previous to her visit to my office she sustained a severe fall; however, she said that she got up and went about her work not feeling any serious inconvenience, but from that time she has not noticed any movement of the child. As there were no distressing or unusual symptoms, I advised her to let matters take their course and await results. She went on in that way until about ten days ago, when I was called in the evening to deliver her. I found her in labor, the bag of waters protruding and the os well dilated; found a small head presenting; ruptured the bag

of waters and there was but a small quantity, 1½ pints to a quart all together, which was clear and not fetid. Delivery was accomplished without difficulty and the placenta came away promptly. I found that the baby was dead, probably at about the seventh month, but was not macerated. When I tied off the cord I noticed close to the body a shriveling of the cord; upon closer examination I found this little specimen and cut it off. Evidently the child had died from the effects of the mother's fall, making several turns, twisting the cord close to the abdomen and the constriction thus produced stopped the circulation.

---

P. Gunterman, M. D., then read a paper on

CHLOROFORM ANÆSTHESIA AND ITS ADMINISTRATION: PART SECOND.

At the previous meeting I had the pleasure of reading about the administration of chloroform. Purposely the anæsthesia from ether was not touched upon. Ether has been used by me comparatively but a few times; chloroform quite frequently. And since these remarks are made mainly to solicit discussion, there is no reason why the ether question might not be also discussed.

The remarks this evening having been very hastily jotted down, only, to my mind, the most salient points have been considered.

Chloroform, if it does kill, does so either abruptly and suddenly or gradually and by degrees. Chloroform is an irritant specific narcotic, one of great diffusibility and capable of quick and excessive action. On the other hand it is progressive in its action, and when administered in proper dose, gradually, the patient is not apt to die from an overdose, but if he does the end may not come so slow as from other narcotics and as from ether.

A person to be chloroformed and made ready for an operation is naturally often unduly excited, because of the chloroform and because of the operation. Such a state of mind is very dangerous and great caution ought to be exercised less we have spasms of the respiratory muscles, failure of respiration from paralysis or syncope. Death may come after the first few whiffs or later, sometimes even after the administration has long ceased and the patient is thought to be recovering. Strong, healthy and robust (especially stout) people who take chloroform for the relief of pain from small troubles, are prone to have syncope. People otherwise constituted, when given chloroform for a short time and short of abolishing completely actual pain, do not often, if ever, have fatal syncope.

We must, as stated the other night, pay close attention to breathing, pulse, the reflexes and the approach of cerebral anæmia. Danger is near from this last source when you notice a peculiar pallor of the face and particularly about the lips, which are firmly drawn, so as to expose the teeth, and give to the countenance a most ghastly expression. The operator may notice, before the chloroformist, that the patient is in danger when the flow from the bleeding artery stops. Change in respiration, faltering of the pulse, and unusual and persistent dilitation of the pupils are indicators of danger. It is said that a patient under the influence of an anæsthetic is at the threshold of death, and a very insignificant peculiarity of his may settle his fate. They do, however, not all die from the effects of the anæsthetic, at any rate conclusive proofs fail as yet. On the other hand people have died on the operating table who have taken no anæsthetic. A patient who dies while taking chloroform may die from other causes.

Patients may die under anæsthesia from heart failure, by paralysis of the respiratory centers, from cerebral anæmia, and from shock. Deaths from heart failure and cerebral anæmia are perhaps the most frequent. If chloroform is to be blamed for all the mishaps ascribed to it, how do we explain the fact that, of the hundreds of thousounds of parturient women, who have taken it, not a single authentic fatal case is on record. It is claimed that their state of mind just fits them for taking the chloroform, that they just suffer enough pain to prevent syncope and that straining at every succeeding pain keeps the brain well supplied with blood. Such is good reasoning. We might, perhaps, conjecture that it is ordained by an all-wise Providence, who is said to have condemned woman to bear her children in pain and agony. These facts ought to serve as proof, to an unbiased

mind, that other agencies and conditions are at work to make chloroform—if you will, any anæsthetic—a bugbear to the operator and cause unjust censure to the administrator for mishaps.

If now accidents do occur, as they have done heretofore, be calm, be cool, be collected, and be deliberate. Have your means of resuscitation at hand. Have your stimulants, brandy, ammonia, nitrate of amyl and nitro glycerine, have your hot bottles and by all means your battery. Be ready to institute vigorous and prolonged artificial respiration. Pull the chin forwards, upwards and with it the head backwards and forcibly draw the tongue forwards. If this mild form of artificial respiration does not succeed use any of the other established methods. Electricity is the great mover and stimulator of the respiratory muscles and nerves, and quite a number of cases are on record where its proper use brought about the desired result. Laryngotomy has been done to re-establish respiration. To relieve anæmia of the brain, reverse the condition of affairs and put your subject in the perpendicular (almost) with the head down. Twice have I seen life come back in a body breathless, pulseless, and apparently dead. Men of worth have fought this method and others as warmly defended it.

Permit me a little pleading for small stimulating doses of morphia, atropia, either—all things being equal—before or after the administration of chloroform. They may produce a general quietude, they may stimulate the heart's action and raise the blood pressure sufficiently, perhaps, to overcome undue depression from the chloroform.

In conclusion: Whenever it becomes necessary to use means of revival be persistant, methodical and—keep on.

DISCUSSION.

Dr. Wm. Cheatham: It is a fact that we do have deaths occasionally from chloroform in the hands of the most careful men, men who make a specialty of anæsthesia. For instance in England, you can refer to almost any issue of the *London Lancet* and it is not an uncommon thing to find from one to five deaths recorded from chloroform, in charge of those making a specialty of this work, showing that there is danger in chloroform outside of the administrator.

As to the method of death: I believe the rule is that patients dying from chloroform anæsthesia die suddenly and we have no time to make an effort at resuscitation. The two facts that we do have deaths from chloroform in the hands of careful, experienced men, and that such deaths are generally sudden, I think is against its administration. On the other side, you take ether in the hands of a man who is accustomed to giving it and if there is any trouble from its administration it comes on in such a manner as to give a man time to make an effort to save his patient. Some years ago I gave ether for a gentleman in New York, and the patient came near dying three days afterward from kidney complication. He was taken sick immediately after the administration of ether and was in a serious condition for three days, then made a good recovery. With chloroform, should there have been trouble, death would likely have come suddenly, and we would have had no time to make an effort to save the patient. In view of these facts I think ether the safest anæsthetic of the two. We have had in this city within the last year, I understand, six deaths from chloroform, all of them occurring before any instrument was used, while preparations were being made for the operation. Some years ago I saw in the city hospital a man who had taken chloroform eighteen times before for the same trouble, (dislocated shoulder) and the nineteenth time he died; death was sudden after taking only a few whiffs of chloroform.

In my practice I use, as you know, very little general anæsthesia, and in recent years I have not had much experience in the use of either chloroform or ether. However, with over three years' experience in the New York Hospital, giving ether three or four times per day, I only saw one accident. Some men admit that the reason they advise against the use of ether is not that it is more dangerous than chloroform, but because it is more disagreeable to the patient. While there may have been some cases where nausea was attributable to ether, still I believe if it is thoroughly watched you are no more liable to have nausea from it than from chloroform.

Dr. A. M. Vance: I think one of the most important parts of surgical work is the consideration and choice of an anæs-

thetic and the person who shall administer it. I know of no other element in the life of a surgeon that gives him more anxiety and more trouble. I use both ether and chloroform, and my choice, except where there are special indications for giving one or the other, is governed entirely by the man who is to administer the anæsthetic. There are men who know how to give chloroform, who practically know nothing in the world about giving ether, and vice versa. Therefore, I think in general surgical practice when we have a man as anæsthetist who knows how to give chloroform and does not know how to give ether, our choice should be chloroform. On the other hand, if we have an anæsthetist who is perfectly familiar with the giving of ether and does not know how to give chloroform, we ought to strain a point in favor of ether, or get somebody else to administer the anæsthetic. I think it is the duty of every operator to require the patient to admit a man of experience as anæsthetist, and we ought as operators to demand a remuneration for that service. I have never seen a death from anæsthetic, that is one that I could say was directly caused from the administration of either chloroform or ether. I have had two deaths on the table in my whole experience, both of which I believe were caused by shock. Both patients were women, one an old lady who had cancer of the lower jaw—a very horrible condition; she was a horror to herself as well as to all her friends; the tumor was protruding from her mouth, producing a condition of druling which was horrible in the extreme; she died just at the close of the excision of that part of the jaw including the growth. Post mortem examination revealed the fact that she had a metastatic condition of the mesenteric glands, liver and probably of the kidneys. She failed to take any stimulation prior to operation, which was advised. The other was a younger women who took ether; the operation was abdominal hysterectomy; patient died just at close of the operation. I want to mention one other case that died a few days after operation for ventral hernia. This patient had slight bronchial trouble; she had been subject of four or five attacks of pneumonia and had lateral curvature. She died three days after the operation from a septic condition seemingly due to the large accumulation of pus apparently in the bronchus, the abdominal wound doing nicely.

Dr. Gunterman's remarks as to the responsibility are not carried out by my experience or by what I have heard in discussions of this matter. He speaks of the anæsthetist being blamed or held accountable for the results in these cases. I think the anæsthetist is rarely blamed for accidents of this character, but the operator is the man who bears the brunt of responsibility. This is very natural, because people look to him for the final outcome of the case. I agree perfectly with Dr. Gunterman that where we have fear and excitement on part of the patient in regard to taking chloroform, we are more liable to have trouble. My experience has been that the administration of morphine or atropine, morphine especially, has some disadvantages. The patient is a longer time in waking up usually and though the condition may be good, it causes a great deal of anxiety on the part of the family and retains the physician there a long time, where it really is unnecessary. I question whether whiskey given with atropine would not be better—I always give whiskey hypodermatically during the operation if at all indicated; rarely give by the mouth before hand.

I also disagree with Dr. Gunterman in the statement that operations done under partial anæsthesia are usually followed by no aggravated symptoms. My experience is that these cases often have more depression and more shock than those where complete anæsthesia is present. It is better to give the anæsthetic to completion rather than do an operation under primary or partial anæsthesia. I would like to emphasize the statement that I think it is our duty, as operators, to require the employment of a man recognized as an anæsthetist, so it may be said, if we do lose a patient, that we had a man of experience for the administration of the anæsthetic, although it may sometimes offend the family doctor or patient who has chosen the administrator of chloroform because of friendliness; this is often the cause of complications, owing to inexperience or lack of knowledge of many men in the administration of chloroform. I think the choice of an anæsthetic should be to the greatest degree determined by the experience of the man whom you are

obliged to accept as an anæsthetist, being of course governed to the proper extent by the special indications in each case; all patients having suspicion of lung or kidney trouble being given chloroform, all those having heart troubles being given ether.

Dr. J. M. Krim: My experience in this direction has been almost entirely with chloroform. I have never seen any unpleasant symptoms, excepting in one case, and have had no deaths. I have had little or no experience with ether, and cannot see why it should be perferable to chloroform. Of course the majority of cases in which I have had occasion to use chloroform have been obstetrical cases.

In regard to a special anæsthetist: We are very frequently placed in a position where it is impossible to obtain such a person, and we have to accept just such assistance as we are able to secure. I have often started the anæsthetic and let a midwife or some one else finish it. Fortunately, I have never had an accident, but of course no one can tell how soon it will come.

Dr. Geo. W. Griffiths: I am still a strong advocate of chloroform as against ether. I cannot give statistics, but as stated at the last meeting of this society, I saw chloroform administered to hundreds and hundreds of men in the late war with only one death that could possibly be attributed to the anæsthetic.

There is one very important point that Dr. Gunterman did not mention in his paper, that is to have blocks or bricks in the room to elevate the table at the foot. I know at the Sts. Mary and Elizabeth Hospital I came very near losing a case that I was about to operate on, some time ago, owing to delay in procuring something with which the table could be elevated in this way. Now we have very high blocks always ready to be placed under the table, which very materially lessens the danger. It may be that I am wedded to chloroform because I have had very little experience with ether. I must admit that since I have seen Dr. Guest administer ether on a great many oecasions, I am more favorably inclined toward its use than ever before.

In regard to the deaths that have occurred in this city recently and elsewhere: It is barely possible that the chloroform might be blamed for it, on account of some impurity. We were preparing to operate some time ago, Dr. Guest will remember the case, and sending to the drug store for ether, they sent us chloroform. It is probable if Dr. Guest had administered the chloroform in the same manner that ether is given (excluding the air), the patient would have been dead. It was a first class druggist or drug store that sent us the chloroform, and his excuse afterwards was that he "did not have any ether, and chloroform was just as good." You must analyze the whole thing, take into consideration the various advantages and disadvantages, previous health, surroundings and everything of that kind in making up your statistics in your condemnation of chloroform.

As far as having a special man to administer the anæsthetic is concerned: This would be impossible in some of my work. My operations are largely "emergency surgery" and I have to pick up the most suitable person I can to give the anæsthetic. However, I think we ought always to agree upon a special man to do that work in the city, where it is possible.

Dr. P. F. Barbour: I believe most of the points have been covered in the discussion this evening and two weeks ago. I believe in children, especially young children, chloroform should be used, as it is much safer than ether. In obstetrical cases chloroform should be used; it is very much pleasanter and is not objectionable on account of danger.

Where you have light or heat from a stove near tbe operation chloroform is indicated, but recent investigations tend to show that chloroform is not entirely safe in close proximity to a flame. The burning of a candle, for instance, seems to convert chloroform into hydrochloric acid and lower chlorides of methane which produce intense irritation of the bronchial membranes, affecting the operator as well as the patient. There are several cases of that kind on record. In military service, I suppose chloroform is much the better because you can work very much more rapidly with it; it is much easier to carry around, and is perhaps safer, as you have not time to inquire whether the patient has kidney, lung and brain trouble.

I would like to call attention to the method McBurney has suggested for giving chloroform or ether; that is by putting an Esmarch bandage around the

limbs and in that way the ether or chloroform is absorbed by only a certain portion of the blood, then when you remove the ligature you have a fresh supply of blood, the patient comes out from under the anæsethetic very quickly, and it also has the advantage that patients can be gotten under the influence of the anæsthetic very rapidly. I saw McBurney put one patient thoroughly under the influence of an anæsthetic in two minutes, and she came out in about the same time.

In regard to the treatment of chloroform poisoning: Electricity of course, is good, also alcohol and digitalis. I prefer strophanthus to digitalis as it is much more rapid in its action. Dr. Gunterman failed to mention one very important aid in the treatment of chloroform poisoning and that is hot applications over the heart; nothing stimulates the heart so much as hot applications.

Speaking of children: I saw Dr. Abbe operate upon a child aged twenty months, in New York, for sarcoma of the kidney using ether as an anæsthetic. I have always thought that was placing the child in very great risk of its life. It had only one kidney by which to eliminate the ether, and it seems to me a strong objection could be raised against the use of ether in cases of that kind. I do not know the subsequent history of the case.

Dr. J. W. Guest (Visiting): All the accidents I have seen from chloroform anæsthesia, which numbered seven and one death, have been very rapidly produced, and I believe this is the rule. In regard to the six cases, referred to by Dr. Cheatham, that died before a knife was used: I do not know of the other five, but do know of one. In this case the operation was completed and the chloroform cone thrown away thirty seconds or more before any serious symptoms were noticed. All at once the heart began to fail and, although every effort was made to save the patient, she died very quickly, and from cessation of the heart's action. Her respiration continued good for several seconds.

Dr. A. M. Vance: Was the patient thoroughly under the influence of the anæsthetic at the time of the operation?

Dr. J. W. Guest: Her conjunctival reflexes had disappeared, stertorous breathing supervened and she was apparently sufficiently anæsthetized for any operation. In fact, she was more thoroughly anæsthetized than the majority of cases to which I administer an anæsthetic, yet not profoundly under it, for during the divulsion she evinced a slight pain.

I believe Dr. Gunterman, in his paper, stated that oftentimes the operator would notice serious symptoms even before the anæsthetist. I can scarcely conceive how this could be if the operator is absorbed in his work and the anæsthetist in his, unless purely accidental. It is usually the case that the anæsthetist is the first to detect serious or unusual symptoms of the heart or respiration, which are not noticed by the operator until his attention is called to them.

I am not an advocate of chloroform, neither am I a confirmed advocate of ether, but believe each case should receive a careful examination and the anæsthetic selected which is most suited to the case. I believe, that in time, other anæsthetics will be discovered which will be found more suitable to certain conditions in life than those we are now using, just as morphine has given way to other drugs. Of course, morphine is still preferable in some conditions, while in other cases there are other drugs which give us better results. I do not think we have a right to say that we will give chloroform or ether, irrespective of the patient's physical condition, surroundings or of consequences. There are many things to be considered. I believe, however, the majority of patients will take ether better and that ether is more suited to the majority of patients than chloroform, especially in extended operations, because it produces by far the less shock and gives the patient a better power of surgical resistance by stimulating, instead of depressing, the system as with chloroform. I want to record myself as believing that chloroform is contra-indicated in every case where ether is not. We should give our patients every possible chance of a safe anæsthesia, and, in view of all statistics collected, I do not see that we can claim that for chloroform. Julliard, of Geneva, in his statistics, reports one death from anæsthesia in 3258 cases where chloroform was used, and one death in 14,987 cases where ether was employed. Nearly five deaths from chloroform to one of ether, and still there are some who claim that chloroform is the safer anæsthetic. In chloroform anæs-

thesia we often hear of serious accidents and difficult resuscitations; where ether is used we seldom hear of these, and yet these accidents are never considered in compiling statistics.

Dr. Jno. Cecil: I feel the burden of responsibility in cases of anæsthesia with any kind of anæsthetic, about as much as in any other situation that comes up in the practice of medicine or surgery. For that reason, I believe the anæsthesia should be in the hands of a competent and experienced person, and he should be well paid for his services. I am inclined to believe that for general anæsthesia, ether is the safer. I do not very well see how we can get around the statistics on this subject, and as has already been mentioned, the method of death and our ability to cope with it, makes ether the safer anæsthetic. Of course, there are always certain general indications to be taken into consideration in the choice of an anæsthetic, but all things being equal I believe ether should have preference. In the majority of obstetrical cases I think chloroform is the safer. Ether, because of its stimulating properties, should be used in the management of cases of severe hemorrhage where any anæsthetic is required. I am inclined to believe there is more danger in the administration of chloroform in obstetrical practice than is usually accorded, and unless I am mistaken, Lusk, in his recent work, reports several cases of death from chloroform in connection with obstetrical work.

The different points have been so thoroughly discussed, that it is unnecessary for me to repeat anything that has been said, but since the last meeting of this society I have had an experience with chloroform that has been the source of considerable anxiety. The case briefly is this: Last Friday, Dr. Frank asked me to see a lady about twenty-five or thirty years of age, who had had a miscarriage and had subsequent hemorrhages more or less profuse in quantity. The patient was the mother of two children. She had some suspicion of lung trouble, perhaps development of phthisis, not well-marked. The patient when I saw her, seemed to be apparently well nourished, color fairly good, considering the quantity of blood which had been lost in several hemorrhages previous to my seeing her. I advised curetting of the uterus; she had been delivered with forceps and had had one previous curetting for some trouble following an abortion a year or so ago, and had conceived a most intense fear of all instruments. I thought a blunt curette would answer every purpose and told her that I believed such trouble as existed inside the womb might be relieved by this means without the administration of an anæsthetic. We found, however, that we could not proceed until we had given an anæsthetic. I had a bottle of chloroform which I had reason to believe was Squibb's chloroform for anæsthesia, bought from a careful druggist. Dr. Frank proceeded to administer this chloroform, giving it to complete anæsthesia; I will say, however, I introduced the speculum and was making the necessary preparations for curetting before she was completely under the anæsthetic, but nothing was done in the way of curettage until she was well under the influence of chloroform. I proceeded as rapidly as possible to curette every part of the uterus, the operation probably not occupying more than seven minutes, but before I had finished the work to my entire satisfaction, Dr. Frank called my attention to the fact that the patient was not doing well, stating that she had ceased to breathe. I asked him the condition of the pulse, and he said then it was fairly good. I immediately withdrew the speculum and curette, and found her with a very weak pulse, perhaps 120 to the minute, and not breathing at all. I had seen people stop breathing and was not particularly anxious about it, but concluded to suspend operations until we could revive her. We grasped the patient each by one arm and leg and let her head drop over the edge of the bed when she immediately gasped and commenced to breathe from that time. After straightening her around on the bed, I felt the pulse and found it much better, probably beating at the rate of 100 or 110 and pretty fair in volume, and again I felt relieved as to the situation, concluding that it was simply one of those little fainting spells which sometimes occur under anæsthesia and was about to proceed when I noticed that she had ceased to breathe again; she would take one deep breath then respiration would cease for half a minute, or perhaps a minute. The most remarkable thing about it was the pulse ranging from 100 to 150 per minute, it would change

from a full round soft pulse in two minutes to a very weak, thready or rapid pulse. This thing kept up and we immediately commenced the administration of restoratives, giving her atropine first in $\frac{1}{100}$th grain dose, which had no beneficial effect, then in two or three minutes we gave her nitro glycerine and digitaline in the same hypodermic, keeping up artificial respiration. Every little while we would tip her over the side of the bed and each time would be rewarded by seeing her come around very promptly, but in a few minutes she would cease to breathe again, and the pulse would likewise fail. We then gave her a hypodermic injection of brandy and placed hot bottles around her. This kind of treatment was persevered in for one and one-half hours before we could safely leave the patient; we finally did leave her in very good condition and had no further trouble in the case.

In my judgment, that woman came very near dying from chloroform, and we afterward learned that on the previous occasion, when Dr. Cartledge did the curetting, she had taken chloroform very badly and had experienced a number of fainting spells afterward. I have often seen irregular respiration under chloroform, but I have never seen the pulse vary as it did in this case. This patient seemed to be in more danger from respiration than from the heart. I simply mention the case as one which struck me as dangerous for the administration of chloroform, and one in which there will be danger every time she takes it. I do not know how ether would do in such a case.

Dr. Gunterman : I favor chloroform simply by preference. I use it a great deal oftener than ether. As far as I can see, it is utterly impossible to make accurate statistics as to the fatality of ether and chloroform, comparatively. There are for instance, forty thousand cases given by Nusbaum that are never taken into consideration in making up statistics ; there are thirty-eight thousand cases of Esmarch's, and a great many others that reach into the thousands, that have never been considered in making up statistics ; there are a great number of cases given by the ordinary physician, and by the small surgeons like myself, which are of course, not considered in statistics.

As to having a special man for this particular work : I said in my first paper that I did not advocate a specialist, but I said at the same time that every physician ought to be thoroughly informed as to how to give it or any other anæsthetic.

In regard to Dr. Vance's remarks that the operator rather than the anæsthetist bears the blame in case of an accident, I must differ : I have seen but one death from chloroform and that was many years ago. Dr. Cowling was the anæsthetist and Dr. Bayless the operator. The patient died very quickly after a few whiffs of chloroform. In this case, the adminstrator of the anæsthetic had to bear the entire burden of responsibility.

Another remark made by Dr. Vance of not giving morphine or atropine as a stimulant in these cases : I must differ with him in this, but I believe these drugs should be given in very small doses, just enough to stimulate the circulation or its action, just enough to produce a little quiet and not sufficient to produce prolonged sleep and in this way prevent us from seeing how our patient is coming from under the anæsthetic.

As to hemorrhage in obstetrical cases : I am satisfied that when you give chloroform in obstetric cases you always have a greater amount of hemorrhage than without it ; where there is any danger of hemorrhage, where you suspect it, whether it be placenta previa or some peculiar condition of the woman, if an anæsthetic is to be given, let it be ether by all means.

---

Quite a sensation has recently been made in Boston by the successful application of wool-fat, or agnine, to the skin, for the removal of wrinkles. When applied with rubbing, it passes directly through the skin and acts as a nutrient to the fatty tissues beneath. An ancient dame has succeeded in removing nearly all the crows-feet from around her temple, and the remedy is fast becoming very popular.

---

The washing of the parts with ether is said to be a rapid and complete method of destroying pediculi pubis.

He who would be strong in mind must have facts for his diet.

## THE MEDICO-CHIRURGICAL SOCIETY OF LOUISVILLE.

*Stated Meeting May 12th, 1893.*

The President, Dr. F. C. Simpson, in the chair.

Dr. T. H. Stucky: In making my round at the City Hospital this afternoon, I found this patient and the case struck me as being one of considerable interest, especially as to the diagnosis which seems to be very obscure. I will read the history as entered in the Hospital record by Dr. Rousey the Interne.

"J. R., residence Louisville, occupation baker; age fifty years. Father dead; cause unknown; mother died of old age. Number in family five, health good. On or about April 1st, was taken with vomiting and pain in the epigastric and hypochondriac regions; bowels regular at this time, but since has had alternate diarrhœa and constipation; stools yellowish brown, high colored. For last three weeks has been worse and noticed tumor in left hypochondriac and epigastric regions; suffered from insomnia, anorexia, coated, flabby tongue. Entered Hospital May 10th; temperature 101½° F; pulse 110; complained of headache and pain in abdomen. On examination found tumor which could be easily outlined by palpitation. When lying on back could easily detect pulsation synchronous with heart beat; tumor movable and gives apparent fluctuation; flatness on percusion; auscultation negative, unless lying on the back, then a transmitted bruit is given. Treatment, salines with big enemas; bowels moved well but not effecting the size or shape of the tumor."

This case seems to me to be of unusual interest. The tumor is very marked; was first noticed about six weeks ago, having grown very rapidly since. There is no history of jaundice.

Dr. A. M. Vance: I think there is an accumulation of fluid, either a cyst or abscess of the liver. I hardly think it the gall bladder.

Dr. A. M. Cartledge: I think there can be no doubt about this being the gall bladder distended with mucus and probably a little bile. It has every evidence of this trouble, tense feeling, fluctuation, etc. and besides it is pretty near the region of the gall bladder, reaching up nearly to the notch in the liver. Ten or twelve weeks ago, I had a case which somewhat resembled this one, except that it did not have the appearance of being cystic as this has. I made the diagnosis of distended gall bladder, cut down upon it and found it was a soft tumor of the omentum. I took out a section of it and the diagnosis was made, by the microscopist, of sarcoma. The most remarkable feature about that case is that the man has steadily improved since the operation, has gained in flesh and really looks as though he was going to get well. The wound closed without any trouble.

Dr. D. T. Smith: It seems to me that the tumor produced by a distended gall bladder would not have so sharp a contour in that position. Again, the other evidences, such as obstructed flow of bile, etc. are not present. There was a case in the City Hospital some years ago, when I was in attendance there, in which some distinguished physicians made an examination and every one of us missed the diagnosis. There was a tumor in the epigastric region and it looked very much like the case before us to-night. Aspiration was practiced on one or two occasions. The man died a few days afterward and the trouble turned out to be an abscess of the left lobe of the liver. I am rather inclined to that opinion in this case, although we know how liable we are to be mistaken in such a condition.

Dr. Dixon (visiting): The case is one of great interest to me. The tumor evidently seems connected with the liver in some way. I do not think it is the gall bladder. I had a similar case in the person of a lady in our town, in which the tumor disappeared under purgative treatment and local applications of iodine. The tumor reappeared, I think, the third time, and each time disappeared under purgation and local applications of iodine. I examined her under an anæsthetic and could trace the tumor up to the notch of the liver, and I am almost certain it was not the gall bladder, neither do I think it was an abscess of the liver. In the case before us I think the trouble is probably abscess of the liver.

Dr. T. H. Stucky: I would like to have had some suggestions as to treatment in this case, whether it would be considered strictly surgical, whether it would be best to aspirate, perform a laparotomy at once, or further try the saline treatment. He was placed upon salines on the night of the 10th instant, which has produced no material change in the stools as to color or character. They have been a little more frequent and more watery. The question with me was whether it is strictly a surgical or medical case.

Dr. J. B. Marvin: In regard to the trouble being in the gall bladder: The point made by Dr. Dixon against that view I do not think is well taken. Not many years ago Dr. Larrabee had a case in a child, having a large tumor in this region which was tapped and reported as a case of abscess of the liver. I took issue at the time and requested Dr. Larrabee if the child died to allow me to be present at the autopsy. In the process of time the child did die and Dr. Larrabee and myself made the autopsy; we found over a quart of fluid in the gall bladder. The cystic duct was obstructed, preventing the flow of bile into the duodenum. The absence of jaundice does not necessarily figure against the idea that the trouble in the case presented is in the gall bladder. I am rather inclined to that view, that it is a distended gall bladder rather than an abscess. I have taken some little pains in looking up reports of abscess of the liver, and have never seen a case where there were not more marked extreme symptoms than this man has complained of.

Dr. A. M. Cartledge: I believe the only way to get at exactly what the trouble is in this case is by an exploration. In the first place, I do not see how it can be retro-peritoneal trouble. In the next place, it seems to be clearly cystic and there is considerable distension. In the third place, the history of the case, if it bears out anything, is one of empyema of the gall bladder. Jaundice does not play any part. This is the very kind of a case in which we have no jaundice necessarily. Probably a calculus has become obstructed in the cystic duct, and the gall bladder is distended with bile and mucus. The gall bladder might be distended in this way and the functions of the liver not interfered with.

# CORRESPONDENCE.

## POINTS OF SIMILARITY.

To the Medical and Surgical Reporter:—I have read the address of Dr Roberts, President of the Philadelphia County Medical Society, upon "Points of Similarity between Us and Homœopathic Physicians" with much distrust in the view advanced.

The burthen of his argument seems to be an apology for the Homœopathic system of medicine, with a wish to receive those who call themselves Homœopaths into fellowship with us.

Nowhere in his argument do we see the moral side brought out to sustain him further in his position. If, as the doctor gives us to understand, these Homœopaths adhere to their peculiar theory in self-limited and minor complaints, but in the graver forms of disease they resort to scientific medicine, the query arises, why do they not discard the name Homœopathy, and come out honestly and show openly to the public where they stand. This species of deception should meet with an open rebuke instead of receiving them into favor. In my observation of this class of Doctors, it has appeared to me that they run their calling for what there is in it financially, without any higher or nobler aim than business.

Where do we see among them any original investigators that have advanced the science of medicine. To-day real Homœopathy is nearly where it started. It was Hahnemannism in the beginning and it is nearly the same now. Does any one man perfect a thing? The past tells us No. The discovery of the germ origin of

diseases together with the many additions to our materia medica lately, and the elegant pharmacy of our drug houses have all combined to alarm them for the safety of their system. Hence they have had to resort to the trickery of trying to deceive the public by calling themselves Homœopaths while in truth the majority of them, the more successful ones, treat their cases scientifically without any regard to their peculiar theory.

A young woman who I met sometime ago, spoke to me of how soon a Homœopath relieved her of a violent headache. She said "he gave me a white powder and in 15 minutes my headache was all gone. The white powder proved to be Phenacetine, thus giving her to understand he used Homœopathic medicine for which Homœopathy received the praise. How can we tolerate this species of deception without a rebuke from us.

If Dr. Jos. Ribb and Dr. W. H. Holcombe told such views as Dr. Roberts gives them credit for why are they appearing as Homœopaths before the world. Have they not a purpose in it, in thus deceiving the public. The system having brought itself into favor mainly by the tasteless form of its medicines, it is resorting to many devices to keep its standing as a separate body. This immoral position the Homœopaths hold before the world, we as physician all see, but the general public are deceived and are not cognizant of it. Hence the large field of practice that many of them have. Having gained a notoriety for using, "easy to take" medicines, they are loath to give up their separate organization, for the system certainly has proved a financial success, as we all see. But can they long maintain this position before the world with this duplicity of action.

I have no doubt Dr. Roberts "*Heartiest handshakes*" would be returned with enthusiasm, for they have all to gain by it and nothing to loose. Therefore I would say let us keep aloof from them until they can come to us honestly and honorably and not in this treacherous way.

I would call the attenion of the readers of the REPORTER to a prize essay upon "Modern Homœopathy, its Absudities and Inconsistencies," by Dr. Browning, of Brooklyn, New York. It will abundantly repay any one who may wish to known about modern Homœopathy, to procure a copy of this essay.

Your Friend,
W. L. MARTIN.

Rancocas, N. J.

## ANÆSTHETICS.

EDITOR OF THE MEDICAL AND SURGICAL REPORTER:—In your issue of May 27, 1893, p. 806, Dr. Gunterman in his article on "Chloroform" writes that Dr. Warren, also of Boston, "did the first surgical operation on a patient under the influence of ether. Sir Jas. Simpson, in 1847, was the first to use chloroform." I do not propose to open the question as to the discovery of modern anæsthesia; I have already treated of the subject in my book "Anæsthsia: Ancient and Modern," which had the honor of being reviewed in your journal of April 29, 1890. But I may draw your attention to the fact that,as I mention in my book, Dr. Long, of Jefferson, Georgia, in March 1842, etherized a patient from whom he painlessly removed a tumor. A very full and interesting account of this operation was published in the *Virginia Medical Monthly* for May, 1877, by Dr. J. Marion Sims, who had the account from Wilhite, of Anderson, S. C., who was an apprentice of Dr. Long and was present at the operation.

In 1831 Professor Ives, of New Haven, used a dilute chloroform—chloricether—as an anæsthetic and his case is reported in *Silliam's Journal* for January, 1832.

How ether came to be used by inhalation for the relief of pain, is told in an old and rare copy of *Beddoe's Journal* which, if time permits, I may some day publish.

Yours Truly
7 Cavendish Row, GEORGE FOY.
Dublin, June 29, 1893.

It takes a fool a lifetime to find out what others see at a glance.

# THE MEDICAL AND SURGICAL REPORTER

ISSUED EVERY SATURDAY

ADDRESS
Care P. O. Box 843, Philadelphia.

HAROLD H. KYNETT, A. M., M. D.,
Editor.

RODERIC C. PENFIELD,
Publisher.

316 - 18 - 20 North Broad Street,
PHILADELPHIA.

TERMS:—Five Dollars a year, strictly in advance, unless otherwise specifically agreed upon. Sent three months on trial for $1.00.

REMITTANCES should be made payable only to the Publisher, and when in sums of Five Dollars or less, should be made by Postal Note, Money Order or Registered Letter.

NOTICE TO CONTRIBUTORS:—We are always glad to receive articles of value to the profession, and when used they will be paid for, or reprints supplied, as the author may elect. Where reprints are desired, writers are requested to make a note of that fact on the first page of the MS. It is well for contributors to enclose stamps for postage, that the articles may be returned if not found available.

SATURDAY, AUGUST 5TH, 1893.

## EDITORIAL.

### PERITONITIS CAUSED BY THE PROTEUS VULGARIS.

Flexner (*Johns Hopkins Hospital Bulletin*, IV, 1893, p. 34) reports a case of peritonitis caused by the proteus vulgaris. The group of bacteria to which this species belongs was first studied by Hauser in 1885, who found the proteus group existing in decomposed albuminous substances. In pure cultures they were found to be able to induce putrefactive decomposition in meat, either sterilized or non-sterilized. There are a number of reported instances in which it appears that this group of bacteria may produce pathogenic changes in human beings. The case which Dr. Flexner reports is a marked example of this and important in bringing out the pathogenic effect of a bacillus usually considered of only saprophytic properties.

The case was in a young woman aged eighteen, white. She was admitted to the Johns Hopkins Hospital on October 29, 1892. When she entered she complained of pain in the abdomen. No history. She died October 31, two days after entering. The autopsy revealed chronic diffuse nephritis: sero-fibrinous peritonit is: acute pleuritis. "Peritoneal cavity—In its dependent portion, about 300c.c. of faintly turbid serum containing flakes of fibrin. The peritoneum congested, the vessels bright red and turgid, and small punctiform hemorrhages are visible beneath the peritoneal coat. Over the general visceral peritoneum there is a fine granular deposit of fibrin which, on removal, leaves the underlying coat of the intestine free from gloss and vividly injected." From the peritoneal exudate cover-glass preparations showed large bacilli only. No bacteria were found in similar preparations from the organs. Cultures were made from the exudate in the pelvis, fromt he peritoneum covering the diaphragm and from the liver, spleen, kidneys and lungs. The cultures from the liver and spleen remained sterile.

The cultures from the peritoneal exudate and kidney developed cultures of the proteus vulgaris. There was a slight

difference in the effect upon milk, but the author thinks them to be identical. Although the culture from the lungs developed coli bacteria, the author thinks that there can be little doubt that the proteus was the cause of the peritonitis.

"The proteus is a widely different organism in nature. It is found in the intestinal canal of human beings, and doubtless under ordinary conditions of health it might find its way into the peritoneal cavity without doing any great damage," but in the case cited the conditions were changed on account of chronic disease.

It is of special interest to know that organisms which do not exhibit under ordinary circumstances any special pathogenic properties in human beings, may, in the altered state of the fluids of the body caused by diseases, produce definite and widespread pathological lesions. Another foe is thus added to those against whom the abdominal surgeon has to contend. Under conditions usually existing, it is the pus-producing and the dirt-loving germs alone with which he has to deal, and with them strict asepsis, the free use of soap and hot water on the hands of the operator, combined with thorough irrigation and drainage of the peritoneal cavity, in those cases requiring it, would seem to be sufficient in most instances. Just how far the proteus vulgaris is accountable for peritonitis following seemingly clean operations remains to be seen, and we wait with interest further investigations of the subject.

## OBITUARY.

Campbell.—On July 14th, 1893, at the N.W. Cor. 10th and Wharton Streets, Philadelphia, J. Moore Campbell, M.D., in the 44th year of his age.

Resolutions of the Jefferson Medical College, Class of 1878, touching the death of Dr. J. Moore Campbell.

Whereas, In view of the loss we have sustained by the decease of our dear classmate and associate in the practice of medicine and of the still heavier loss sustained by those who were nearest and dearest to him, therefore, be it

*Resolved*, That we tenderly condole with the family of our deceased classmate in their hour of trial and affliction and commend them to the keeping of Him who looks with pitying eye upon the widowed and fatherless.

*Resolved*, That in our natural sorrow for the loss of our esteemed classmate, a faithful and eminent practitioner of medicine—believing the world is better he having lived in it—that we find consolation in the belief that it is well with him for whom we mourn.

*Resolved*, That this heartfelt testimonial of our sympathy and sorrow be forwarded to the family of our departed classmate by the President of the Jefferson Medical College, Class of 1878, and be printed in the Medical Journals of Philadelphia.

L. Webster Fox, M. D., *President.*

H. A. Brous, M. D.,
A. H. Hulshizer, M. D., } *Committee.*
J. A. Wamsley, M. D.,

### Hypodermic Injections of Iron in Anæmia.

Dr. Dantz, of Brussels (*La Semaine Medicale*), in two cases of very intense anæmia, in two working girls, has obtained rapid and considerable improvement from hypodermic injection of the following:

℞ Citrate of Iron.....gms. 2 (grs. xxx).
Distilled water.....gms. 30 (℥i).

Half a syringeful subcutaneously every two days.

### Local Syphilides of the Scalp.

Dr. Rietema (*Deutsche Med. Wochenschr*), in local syphilides of the scalp, employes the following salve:

℞ White precipitate.....gms. 4 (℈j).
Corrosive sublimate.....gms. 0.2 (grs. iij).
Vasoline, } aa..... gms. 20 (℥v).
Lanoline, }
Oil of roses.....gtts. 5.

Wash the scalp with a solution of the bicarbonate of soda, and then rub in this salve.

# ABSTRACTS.

## TREATMENT OF LOSS OF SEXUAL POWER BY LIGATION OF VEINS.

The loss of sexual power, says Dr. Alfred King (*Boston Medical and Surgical Journal*), or rather deficient erections of the penis, render so many men miserable mentally and physically, that any new method of treatment, promising a radical cure, merits investigation and trial.

Three immediate causes of deficient erections may be specified: destruction of the erector muscles, loss of nerve power, and a change in the circulation. The first of these is so rare and so easily determined that it needs only a passing notice. The second cause, loss of nerve power, seems to me to have received more prominence than it deserves, as it is the basis on which almost all treatment is founded. While its force in many cases is undisputed, yet the frequent failure of treatment based upon it leads me to direct attention to the importance of the third cause, that is, a change in the circulation. This change takes place in the veins, especially those which do not pass beneath the pubic arch, or are not acted upon by the erector muscles. Repeated engorgement of the penis renders their calibre larger and, consequently, there is a more rapid escape of blood through them. When, therefore, an erection takes place, it cannot be maintained on account of the escape of blood through these channels. Thus we have the history of a gradual shortening of the duration of erections, and, finally, scarcely none if any, as these veins grow larger.

The remedy for such a condition, especially when far advanced, is not in the use of drugs, but may be brought about speedily and safely by the ligation of some of the larger of these veins.

The following case is given to illustrate this cause and its successful treatment:

Mr. M., aged thirty-five, a laborer of powerful physique, came to me about a year ago with the following history: For several years he had been losing the power of maintaining an erection, during the past year its duration having been so short that sexual intercourse had been rendered impossible. There was a loss of sexual desire and great mental depression. Excessive use or abuse was the cause of this condition.

I gave all possible encouragement to the patient; advised total abstinence from sexual intercourse, cold baths (especially to the spine and external genitals); prescribed bromides, cannabis indica, cantharides, damiana, phosphorus and salts containing it; pushed strychnine as far as it could be borne; gave various tonics; used electricity; and, in short, tried everything which offered any hope of success, but all to no effect so far as producing any stronger erections was concerned.

Careful study of the case convinced me that the immediate cause of the trouble was a physical one, due to a leakage, as it were, or to a too rapid escape of blood from the penis when erected. I, therefore, determined to ligate a couple of the larger subcutaneous veins at the base of the penis and watch the effect.

This was very easily done by the use of cocaine. A vein on each side of the penis was exposed, ligated in two places and severed between the ligatures. A dressing was lightly applied and held in position by a strip of adhesive plaster placed longitudinally. The result was immediate. In less than five minutes after leaving my office he had an erection. That night he was awakened by a powerful erection which made the bandage so painfully tight that he was obliged to jump out of bed onto the cold floor to subdue it. Primary union was prevented by the frequent erections, but the success of the operation was certain.

Two months later he reported himself well, mentally and physically; his sexual appetitite had returned, and since the operation, his power of maintaining erections had been as good as ever.

### To Hasten Desquamation in Scarlatina.

The following is recommended:

℞ Resorcin ..... ℥ij.
Lanolini ..... ℥iss.
Olei sesami fl ..... ℥ss.

Mt et. ft. ung.
Sig.—Rub into skin.

## COCAINE IN GENERAL MEDICINE.

The following is a summary of the uses of cocaine in general practice, as elicited by the experience of Philadelphia physicians, collated by Dr. L. H. Adler and reported in the *International Medical Magazine.*

In several cases of chronic alcoholism cocaine did not appear to have any effect, or, if any, but an indifferent result in relieving the nervous depression and the craving for stimulants.

In the tickling cough of an acute angina cocaine acts promptly.

In two cases of asthma with moderate emphysema, a 2 per cent. solution applied to the Schneiderian membrane, promptly relieved the attack and seemed to delay its recurrence.

In chronic Bright's disease, complicated with typhoid fever and suppression of the urine, cocaine in $\frac{1}{8}$ grain [8 mg.] doses (in addition to the digitalis and whisky previously employed) produced a copious secretion of urine within a few hours after its use. Good service has been had from cocaine in the anasarca from acute Bright's disease. In chronic Bright's disease (of both the parenchymatous and interstitial varieties) the drug causes a marked increase of the daily excretion of urine.

Cocaine is of no benefit in the cough due to bronchitis.

In cardiac dropsy, cocaine is of use as a diuretic, and especially is this noticeable in cases in which the pulse is feeble and the heart's action weak. In these cases, $\frac{1}{4}$ grain [16 mg.] doses, increasing to 1 grain [6 ctg.], were administered every 2 or 3 hours.

As a cardiac stimulant cocaine is not only usful but it is prompt and decided in its action. To this statement, however, we find several exceptions taken.

Dr. F. A Packard believes the drug to be useless as a heart stimulant, and Dr. Charles W. Dulles was disappointed in its employment for this purpose in a case of cardiac weakness associated with valvular insufficiency. Dr. James C. Wilson employed the drug a number of times in the latter stage of enteric fever, to combat the tendency to cardiac asthenia. For this purpose he administered it by the mouth and hypodermatically in doses of $\frac{1}{6}$ grain, [1 ctg.] repeated every 2-4 hours, or, where the effect was pronounced, at somewhat longer intervals. In a fair proportion of the cases, the drug appeared to have the properties of a cardiac stimulant; in other cases no obvious results followed its use; and in a limited number of cases its effect upon the circulation appeared to be distinctly depressant. Dr. Wilson believes the depression effects observed in certain cases to be due to idiosyncrasy.

In the vomiting of gastric catarrh, alcoholic or otherwise, cocaine $\frac{1}{4}$ – 1 grain [1.5–6 ctg.] doses, given alone or with bismuth, on an empty stomach, has given instant relief.

In acute nasal catarrh, cocaine, used in the form of a spray (10 per cent solution), has not only relieved but cured the catarrh.

As a cerebral restorative or excitant, the coca-leaf, in the form of a reliable extract, alcoholic or aqueous, is to be preferred to the alkaloid. The fluid extract of the coca-leaf seems to contain other principles and to differ from cocaine in its action almost as opium differs from morphine or cinchona from quinine. Dr. James H. Lloyd believes cocaine to be very potent as a brain stimulant, but he thinks that its use as such is apt to do more harm than good.

As a temperature-elevator in cases of general collapse, cocaine is useful.

The concensus of opinion seems to be opposed to the use of cocaine in the nares unless extreme care be observed and the patient be kept in ignorance as to the remedy employed. In two cases of coryza, in which the drug was used, toxic symptoms ensued. The strength of the solution used in one case was only 2 per cent.

In chronic cystitis, cocaine will afford temporary relief when injected into the bladder, but it must be used with care and caution.

Cocaine has been used in cases of debility of old age. In combination with strychnine and quinine, in doses of $\frac{1}{8}$ grain [8 mg.], it has been found to be a safe and good tonic. Dr. J. Cheston Morris does not think it equal in these cases to the elixir of ammonium valerianate.

In the dropsy of both renal and cardiac origin, the internal use of cocaine, in solution or pill form, has proved a useful diuretic when given in doses of $\frac{1}{6}$-$\frac{1}{4}$ grain

[8-16 mg.] every 2 hours. Even in cases of complete suppression of urine, which was not relieved by the use of digitalis and whisky alone, cocaine, given in the manner and dose mentioned, soon caused the urine to be secreted.

Cocaine, in the form of a suppository, has been used with some advantage in relieving the tenesmus of dysenteric disorders, especially in the entero-colitis of children.

Good results have sometimes followed the use of cocaine in the several varieties of dyspepsia. The dose employed has been ¼–1 grain [1.5–6 ctg.], repeated several times a day. Dr. S. M. Wilson states that in cases of dyspepsia where much general weakness was complained of, the administration of cocaine gave temporary relief only; later on the stomach-trouble seemed to be aggravated.

Sometimes a single dose of cocaine will stop the nausea and retching following ether-anæsthesia. In other cases ¼ grain doses [1.5 ctg.] will have to be given hourly.

Wine of coca has been found superior to other remedies in relieving the suffering from hectic fever.

Cocaine has been found of service as a general stimulant in cases of exhaustion occurring during the course of prolonged diseases, such as typhoid fever, particularly when collapse was threatening. In febrile conditions accompanied by irritability of the stomach, the use of the drug, ten or fifteen minutes before giving food, will enable nourishment to be retained when otherwise it would be rejected. To combat the tendency to cardiac asthenia occurring in the later stages of enteric fever, cocaine may be given by the mouth or hypodermatically in doses of ⅙ grain [1 ctg.] every 2 or 4 hours. In the tremor following typhoid fever, cocaine in some cases seems of permament benefit, and in others its effects are only transitory.

Cocaine is useful in many cases of vomiting dependent upon gastric irritability. It is advisable, in cases of violent nausea and emesis attendant upon gastric irritation from the ingestion of faulty articles of diet, etc., to precede the administration of the cocaine by lavage, in order to get rid of the irritants before applying the sedative. In cases of sympathetic vomiting this preliminary cleansing of the stomach is not necessary. The dose of the drug is $\frac{1}{16}$-¼ grain [4–16 mg.] in one or two teaspoonfuls of water.

Gastritis.—Excellent results have been obtained from the use of cocaine in those cases of gastritis in which the drug could exert a direct local effect.

In cases of gastrodynia, cocaine in ¼–1 grain [1.5-6 ctg.] doses, given alone or in combination with bismuth, on an empty stomach, has given instant relief.

In hay-fever, where there is often a markedly neurotic element, Dr. J. H. Lloyd believes that the relief obtained from the use of cocaine is often followed by a reaction which leaves the patient distinctly worse. This gentleman states that he has never known its use to cure this disease. In the asthma of hay-fever, Dr. James M. Anders has found of service a 2 per cent solution of the drug applied to the nares.

As a brain-stimulant, cocaine should not be employed in hysteria, both because its relief is slight and temporary, and especially, because of the danger of forming the cocaine-habit.

In two cases of impotence, wine of coca was given a full trial, but without obtaining any result.

Cocaine has been beneficial in hyperæsthesia of the larynx and pharynx when unaccompanied by any structural lesion in them or in any other organ. The drug should be given in doses of from $\frac{1}{16}$–$\frac{1}{10}$ grain every 4 hours.

Cocaine has been used in melancholia with negative results, except in the acute forms of melancholia agitata, when its employment seemed to give ease to the patient.

Cocaine has been used to combat the opium-habit; the plan of treatment being a descending dose of opium, and an ascending dose of cocaine. The limited experience had with it in these cases is rather unfavorable to its employment.

Cocaine as a spray to the throat and larynx in the sore-throat of advanced phthisis is a temporary relief. Its action, however, is very fugacious, and the patient is apt to want it constantly. Combined with cubebs and morphine, in the form of troche, cocaine in $\frac{1}{20}$ grain [3 mg.] dose, has relieved the cough of phthisis. In the distressing vomiting so often seen accompanying pulmonary phthisis, which is due to the cough, cocaine has been given, but not with satisfactory results.

For the vomiting of pregnancy cocaine occasionally gives relief, but more often it fails. It is probably in the neurasthenic class of these cases, as pointed out by Dr. William L. Taylor, that cocaine is useful. It should be given by the mouth in doses of $\frac{1}{10}$-$\frac{1}{4}$ grain [6-15 mg.] every 2 or 3 hours. It may be advantageously combined with monobromated camphor (1 grain [6 ctg.]) or zinc phosphide ($\frac{1}{10}$ grain [6 mg.]).

Cocaine given by the mouth in doses of $\frac{1}{8}$ grain [8 mg.] has been successful in relieving severe pyrosis.

In cases of œsophageal stricture, cocaine has been used with benefit for two purposes: to allow of the painless passage of the œsophageal bougie, and to enable the patient to eat with comfort by relieving the additional spasmodic constriction which is produced by the contact of food with the mucous membrane of the œsophagus.

Results obtained from the use of cocaine as a general tonic have varied, being favorable and otherwise. When employed for this purpose, cocoa should be given in the form of the wine or in the form of a reliable fluid extract, alcoholic or aqueous.

Indifferent effects have been noted as a result of the use of cocaine in tremor following typhoid fever.

In the pain and vomiting of gastric ulcer cocaine in $\frac{1}{4}$-1 grain [1. 5-6 ctg.] doses has proved very effective. Its administration has also enabled the patient to eat and retain an increased amount of nutriment.

## A METHOD OF TREATING COMPOUND FRACTURES.

The method aims at being simple, and in the following account it may be considered as applied to the commonest of compound fractures, viz., those of the leg. On admission, the limb is covered with lint soaked in carbolic lotion and is subsequently cleaned with the greatest care; protruding bone is replaced, loose or damaged bone is removed, and the broken ends are adjusted by means of splints with as little delay as possible.

1. Ordinary well-padded wooden splints are employed, but under no circumstances is the limb secured to the splint by means of strapping. Strapping may be used to form a stirrup whereby extension may be applied in the fractures of the femur or humerus, but no other forms of plaster appears to be other than objectionable when the question of fixing the limb is concerned. If the strapping be adjusted with sufficient firmness, it will often be found that within twenty-four hours the limb has swollen and the strips of plaster are cutting into the soft parts and are impeding the circulation. The strapping then has to be cut or reapplied, and a second adjustment of the limb is rendered necessary. On the other hand, in process of time, the band of strapping is found to have come loose from shrinking of the limb, and a further readjustment of the fractured parts is called for. In the place of plaster, straps of fine webbing and buckles are made use of to secure the limb to the splint. These vary in length, and are applicable to all parts. If found to be too tight or too loose, they can be altered as often as necessary in the day without the least disturbance of the limb. In this way the limb can be secured with a proper degree of firmness. Where the webbing crosses the shin or the dorsum of the foot, a small shield made of gutta-percha, and lined with lint, is interposed. When side splints are employed, these also are held in place by straps and buckles. No bandages are ever applied. They are quite unnecessary. They cannot be readily tightened or loosened, and they cover up to an undesirable extent the damaged parts.

2. In the second place, the limb is kept throughout in the open air. This would happen by necessity, more or less, in the case of the upper limb, but it is insisted upon also in all fractures of the lower limb in which there is a wound. If the principles of aseptic surgery be well founded, a worse atmosphere with which to surround a wound could scarcely be found than that which exists under the bedclothes. This atmosphere is confined, is hot and moist, and when flatus is passed or the bed-pan is used must of necessity become especially offensive. In all compound fractures of the leg or thigh, the limb is kept throughout entirely uncovered

as well by night as by day and in the winter as in the summer. In cold weather. the nurse makes a cotton-wool cap for the foot, but during the six years in which this rule of uncovering the limb has been observed there have been no complaints of chill or evils arising from exposure. It might be mentioned that in the author's wards in all cases of wounds of the lower limb, including amputation wounds, and in all cases of ulcer, the part is kept throughout the whole period of treatment uncovered save by the necessary dressings, and since this plan has been adopted the results have been infinitely improved.

3. The third element in the treatment concerns the treatment of the wound. In cases of compound fracture there is usually a not inconsiderable amount of bleeding and oozing from the wound which will often be continued for many days. It is very desirable that this fluid should not be pent up in the limb, and that it should be allowed the freest possible means of escape. The plan of lealing the wound with collodion may be spoken of in general terms as bad. It can in no way control the oozing, which may long continue from the damaged parts, and merely confines within the recesses of the limb a fluid which is admirably adapted for the development of bacteria.

While a free exit should be given for all discharges of blood and serum, such a barrier must, at the same time, be erected as will prevent the entrance of pus-producing bacteria. A dressing of antiseptic gauze wool may possibly meet these conditions, but in a large proportion of cases isucha dressing needs to be very frequently changed, and such a change cannot always be effected without disturbing the position of the broken bones and putting the patient to no little inconvenience.

In the present collection of cases, the wounds have been simply covered with a heap of dry antiseptic powder, which has been applied without stint. This covering of powder may be considered to seal the wound, so far as the possible entrance of bacteria is concerned, while at the same time it in no way impedes the free escape of blood and serum from the damaged parts.

The discharge finds its way into the protecting powder, and forms with it a harmless scab or crust. As the powder becomes saturated, more and more of it is applied, but the crust produced is not disturbed. In certain cases the oozing continues for many days, and in one or two instances the crust produced has exceeded the size of the adult fist. The powder employed has been iodoform or creolin. The latter has been found to be the more convenient. For the first few days the powder may need to be dusted on every few hours, and as the limb is kept always uncovered the saturation of the crust can be at once noticed. When no more blood is found to be escaping the powder is discontinued, and some seven days after this period the artificial scab is removed and the wound beneath may be expected to be healed or to be healing.

When the laceration occurs upon the upper surface of the limb there is no difficulty in covering it with powder. When it is placed upon the sides of the extremity a platform of cotton wool must be so fixed in place that the powder, when dusted upon it, will bury the wound. The cotton wool may be kept in position by fixing it in position against the side of splints, or by attaching it to the skin by gum.

The following advantages may be claimed for this method: It is simple, and requires but the simplest appliances. The fracture, when once adjusted, need not be again disturbed. The damaged part is kept exposed to view, and the position of the ends of the bone can be ascertained at any time.—Frederick Treves, F. R. C. S., in *Annals of Surgery.*

---

### Acute Rheumatism.

*Le Progres Medicale* gives the following:

1. ℞ Tinct. aconite.....gms. 12 (℥iij)
Destill. extr. hamamelis.....gms. 90 (℥iij).
Alcohol.....gms. 60 (℥ij).

Liniment. Apply locally and cover the joint with a flannel.

2. ℞ Phosphate of Iron.....gms. 0.3 (grs. v).
Bromide of lithia.....gms. 25 (℥vj).
Distilled water.....gms. 120 (℥iv).

A teaspoonful every two or three hours, in water.

3. ℞ Salicylic acid, Bicarbonate of soda, aa.....gms. 8 (℥ij).

Sufficient for twelve powders. One every two or three hours.

---

### For Shock Following Abdominal Operations.

Dr. E. P. Davis gives the following in cases of slight shock following abdominal operations:

℞ Elixir ammonii valerianati.....℥j.
Spirit frumenti.....℥ij.
Aqua bullient.....℥ij.

M. Sig.—As an enema every two hours.

## WHEN AND WHY THE BABY SHOULD HAVE A DRINK OF WATER.

CHARLES G. KERLEY, M. D.

Does the thought of giving the baby, whether sick or well, a drink of water ever occur to the mother of a nursing or bottle-fed infant? This question can be answered, with but few exceptions, in the negative. Does it occur to the physician to suggest the same for his little patient? Comparatively seldom. The idea that an infant should not have plain water to drink is so thoroughly grounded in the minds of many people that they rebel when it is suggested to them. In an experience with several hundred mothers of young babies, both in institutions and in private life, I have met with but very few to whom the idea had ever suggested itself. The opinion seems to prevail among the better class that a babe less than one year of age should get nothing but milk or some one or more of the liquid foods. A great many of my dispensary patients are given everything drinkable but water.

Every physician who has much to do with children has often elicited the following history of his patient after a careful inquiry: The bottle-fed infant was taken sick with some slight ailment accompanied by fever; perhaps there was a slight bronchitis, or a tonsilitis, or a dyspeptic catarrh; at all events the child was feverish and thirsty; the usual amount of milk, at other times sufficient, now did not satisfy; the baby cried for the bottle after feeding, and was only appeased by an extra allowance of milk. This indulgence was continued for a day or two, and was followed by diarrhœa and vomiting, directly produced by the repeated overloading of the stomach, the severity of the attack varying according to the condition of the child, the season of the year, the nature of the food given and the surroundings. The crying for the bottle was interpreted by the mother as a call for more food, and as the crying was stopped when it was given, the process was repeated. The babe did not require more food; it was thirsty and would have been just as well satisfied with a tablespoonful or two of water, and the unpleasant, if not dangerous, results of overfeeding would have been obviated.

So thoroughly have I become convinced of the great benefit derived from giving water to sick babies that I now order it in nearly every case with fever, and it is astonishing to see how the restlessness and many of the symptoms we are apt to attribute to pain and fever disappear when it is given freely. By freely I mean from ½ to 2 ounces immediately after or between the feedings. If given immediately after the feeding a smaller quantity will, of course, be required. Time and again I have seen infants with measles, scarlet fever or pneumonia, after a period of great restlessness, fall into a quiet sleep when a couple of ounces of cool water had been given.

In summer diarrhœa, the so-called cholera infantum, with the large watery evacuation, the loss of fluids from the body is enormous. In such cases, the little patients take the water ravenously. I have given babies eight to twelve months old, with severe diarrhœa, from 4 to 6 ounces of water every two hours, alternating with the sick diet, which was also a fluid. Sometimes after taking such a large amount the child will vomit, especially if it is handled a great deal. The patient should, therefore, be kept absolutely quiet; but if vomiting occurs it can do no harm; in fact, it may be beneficial, as it serves to wash out the stomach, possibly removing curds and offending material, and so taking the place of a stomach washing. After a few minutes of rest a couple of tablespoonfuls may be given, and will almost always be retained.

In some forms of illness it is necessary to diminish the amount of food given. In these the loss in bulk should always be substituted with water. During the hot months of July and August the breast-fed infant is apt to be nursed too frequently or too long at a time, consequently overnursed—more milk is taken than is required. If a few teaspoonfuls of water are given after it has nursed the proper time, the babe will be just as well satisfied. Or if too frequent nursing is the trouble, a small amount given between the regular nursing hours will enable the child to go the usual time without inconvenience. If this is done, the babe will not be overfed; and, further, the water, if given immediately after the nursing, will assist in

the digestion of the milk by causing the curd to form in smaller masses, and it is, consequently, much more easily acted upon by the stomach juices, thereby helping to keep the stomach in a healthy condition, the chances for serious trouble being thus largely lessened. If a drink or two is given at night during the excessively hot weather, it will help to break up the pernicious habit of frequent night nursing, produce sleep and comfort for the child and much-needed rest for the mother.

The water to be given should be boiled, put in a cool place and kept carefully covered. It should never be given very cold. It will usually be well taken from an ordinary nursing bottle at a temperature of 50° to 70° F. Some babies will not take the water at all, at first, if it is cool; in such cases, of course, it can be warmed. It will readily be seen that the advisability of giving the baby water to drink when indicated as above is unquestionable. Harm it cannot do.—*Mother's Nursery Guide.*

## THE INFLUENCE OF DISEASE OF THE EAR UPON THE DEVELOPMENT AND COURSE OF INSANITY.

The following is an extract by Ireland (*Journal Mental Science*), from a resume of Dr. Bjeljaknow (*Boston Med. and Surg. Journal*), who has studied the subject in a hospital of St. Petersburg. He has confined his observations to cases where there was distinct inflammation of the middle ear.

Out of the post-mortem examinations which he made during four years, 17.12 per cent. suffered from internal otitis. Of these, one of the patients had melancholia, one paronoia hallucinatoria acuta, eight paranoia hallcinatoria chronica, two secondary dementia, three epileptic insanity, four general paralysis, one acute delirium, one senile dementia and three hebephrenia.

The author, at the end of his paper, gives the following conclusions:

1. An inflammatory process of the internal ear is frequently the cause of mental derangement, especially of insanity accompanied by hallucinations.

2. If the local inflammatory process takes an unfavorable course, the insanity often passes into secondary dementia, which, otherwise, this form of insanity is not so liable to do.

One-sided hallucinations of hearing are very frequently the result of a heightened excitability of the cortical centers, the result of the transmission of the irritation from the auditory nerves.

3. Hallucinations of hearing on both sides, which support the hypothesis of the independent function of each hemisphere, may be caused through disease of the auditory apparatus.

4. Irritation of the organ of hearing frequently does not stop at exciting hallucinations of hearing, but as a result of the influence of this sense upon the other, it also excites other hallucinations, especially those of taste, smell and general sensibility.

The character of the delusions of the sense is tinged by the personality of the patient.

5. In many of these patients who suffered from ear disease, there was found a hyperesthesia of hearing which, as a sequel to noises or musical sounds in the ear, becomes changed into a diseased sensation.

At the same time, the sensibility to hearing outward sounds is not increased, but, for the most part, diminished.

6. The overflow of saliva, which often accompanies suppuration of the middle ear, is caused by irritation of the chord and the nerves of the tympanic plexus.

The hypochondriac depression and pain about the pericardium, which from time to time trouble these patients, may be explained through irritation of the nervi-vagi of the auricular branch and the propagation of this irritation to the auditory brain centers.

7. The connection of disease of the ear with insanity accompanied by hallucinations is only observed in cases where mental activity and apprehension are not yet much diminished.

8. Epilepsy seems sometimes to depend upon disease of the labyrinth.

The irritation, coming from inflammation of the middle ear, may assume the form of a false general paralysis.

9. Hallucinations of hearing, though rare in general paralysis, may, when they appear, be the result of otitis on one side. In this case the hallucination is generally confined to the same side of the brain.

# SELECTED FORMULÆ.

### Cutaneous Diseases.

Nothing is better, says A. T. Thompson, to allay itching in cutaneous diseases than the following:

℞
Plumbi acetatis.....grs. xvj.
Acidi hydrocyanici diluti.....ʒjss.
Spiritus rectificati.....ʒiv.
Aquæ destillatæ.....ʒvijss.

M. Sig.—Fiat lotio.

### Prevention of Boils.

Dr. Rosenbach (*Munch. Med. Wochenschr.* No. 8, 1893), in order to prevent the development of crops of boils, in the back of the neck and nose, especially advises persistently rubbing the region attacked with some fatty substance, as cold cream, *lanoline*, unsalted butter or lard. Lanoline, above all is to be preferred. The development of boils is due to dryness of the skin, and by inunction of a fatty substance the dryness is removed and the penetration of micro-organisms prevented.

### For Chronic Bronchitis and Emphysema.

The following is recommended:

℞
Ammonii carbonatis.....grs. iv.
Tincturæ scillæ.....mxx.
Spiritus ætheris.....mx.
Tincturæ nucis vomicæ..... mx.
Infusum serpentariæ ad.....ʒj.

Misce et fiat mistura.
Two tablespoonfuls every six hours.

PROF. GRAHAM ordered the following as a dusting powder for syphilitic eruptions on a child.

℞
Acid boraric..... ʒ ij
Hydrarg chlorid mitis ..... ʒ ij
Lycopodii ..... ʒ vj

M. Sig. Dust on the parts affected night and morning

### Atrophic Rhinitis.

℞
Thymol ..... grs. jss.
Alcohol, } ..... āā ʒjss
Glycerini, }
Aq. dest ..... ʒj

Use as a spray.

### Zinc Glue.

Trentler recommends a preparation, first suggested by Una, for stiff surgical dressings suitable for fractures and dislocations:

℞
Oxide of zinc ..... 10 parts.
Gelatine..... 30 parts.
Glycerine ..... 30 parts.
Water ..... 30 parts.

Apply thickly, rubbing into the muslin or gauze forming the bandage.

—*Ex.*

### Enlarged Tonsils.

Dr. Moure cauterizes with this:

℞
Trichloracetic acid.....gr. i ss.
Iodine .....gtts. iv.
Iodide potash.....grs. viij.
Glycerin.....fʒii¼.
Distilled water.....fʒiiss.

### Nocturnal Sweats of Consumption.

Dr. Ewart (*La Sem. Med.*) speaks highly of the following pill, in the night-sweats of consumptives:

℞
Sulphate of quinine, }
Sulphate of zinc, } aa. gms. 1.5 (grs. xxij.)
Ext. of hyoscyamus, }
Ext. of nux vomica....gms. 0.5 (grs. vijss.)

Make sufficient for twenty pills. Two pills on retiring.

### Herpes Zoster.

Broca recommends the following in herpes zoster:

℞
Acid. boric.....ʒss.
Zinci oxid., } aa.....ʒj
Pulv. amyli, }
Vaselin., pur.....ʒiij.
Lanolin.....ʒivss.

M. Ft. unguent.

### Aqua Picis in Cholera.

Polubinski has observed in choleratic patients real benefit from the use of tar-water, which he gave internally, in small quantities, in form of clysters. It many times arrested violent diarrhœa and vomiting, and improved the *bien-etre* of the patients.—*Trans. Omsk Med. Soc.*, Vol. ix, No. 9.

### Bites of Insects.

Dr. E. Lang (*La Sem. Med.*) praises the following preparation in the bites of insects:

℞
Liquid ammonia.....gms. 3 (gtts. xlv.)
Collodion.....gms. 1 (gtts. xv.)
Salicylic acid.....gms. 0.1 (grs. jss.)

Apply a drop upon each bite.

—*Pritchard.*

### Constitutional Syphilis.

A mixture often ordered by Dr. Keyes is as follows:

℞
Potass. iodid..... .....ʒij
Ammonii carbonatis.....ʒss.
Tr. cinchonæ comp.....ʒiv.
Syr. aurantii cort.....ʒjss.
Glycerine.....ʒj.

M. Sig.—A teaspoonful, well diluted, after each meal.

# CURRENT LITERATURE REVIEWED.

THE CHICAGO MEDICAL RECORDER

for July. Dr. Archibald Church contributes an article on

**The Removal of Ovaries and Tubes in the Insane and Neurotic,**

in whch he comes to the following conclu sions:

1. The removal of the adnexa is not justifiable in cases of pure functional neurosis. 2. Even when appreciable disease of the tubes and ovaries is present, an operation should not be performed until palliative treatment has first been tried. The results in hystero-epilepsy and hystero-mania are so uncertain that celiotomy is not to be advised.

Dr. Edward Wyllys Andrews discusses

**An Improved Operation for Varicocele.**

The operation is described as follows:

The redundant scrotal skin is grasped as in preparing to apply the clamp. Having crowded the testes upward until there appears but little more room for them, and it is apparent that the skin over them is reasonably tense, the part below this is marked for removal with all such veins pertaining to the varicocele as can be taken up with it. Now, intead of the clamp, a line of sutures is made to separate the portion to be removed from that above, the line being carried from the perineum forward in a curve to some point below the bulb of the penis.

If quilled sutures are inserted they should be placed one-half an inch apart and drawn not too tightly.

The plan the author prefers is to thread two silkworm guts upon straight needles and tie the other ends to each other, thus getting a long piece with a needle at each end. Beginning at the perineal end, the double stitch is now carried forward in loops of one-half or five-eighths of an inch in length, the needles inserted being from opposite sides and crossing each other each time until the front is reached, where the free ends are tied to each other.

One reason for preference for this form of deep suture is because it shortens the line as well as compresses laterally by a sort of puckering string action.

Having secured contact of the two sides of the scrotum by this permanent substitue for the clamp, it only remains to divide the skin, and contained varices, about half an inch below this line and secure all bleeding which the compression of the deep sutures may permit, after which a continuous horsehair or other superficial suture will complete the operation.

The author states that his success with this operation has been perfect. Union of the superficial wound usually takes place in five or six days, but the author prefers to leave everything untouched for about fourteen days, removing everything at that time, including the retention sutures, and sealing with collodion any small unhealed spot.

The operation should be done with rather minute care, especially in the final step of approximating the scrotal skin which is thin and needs careful suturing with a fine needle and very numerous small stitches to insure nice closure. It is well to use a few horse-hair drains of a dozen or two fibres each, to remove the excessive serum by capillarity and prevent local distension.

Dr. A. E. Hoadley reports "Six Cases of Metatarsalgia." In one case the pain was relieved only by the resection of a small neuroma on the digital branches of the plantar nerve. The other cases recovered by the use of a properly fitting shoe provided with a stiff sole to prevent bending of the foot.

Mr. Ernest Hart, of London, contributes a most able article on "The Health Conditions of Chicago." With his characteristic clearness, he points out the great danger from the water supply and the constant danger of its polution by sewerage from the Chicago River. He also shows that the typhoid mortality of Chicago is above that of any great city of the world. He urges that the cribs for the intake of the water supply be all moved out four miles into the lake and that a system of subsidence and filtration be established.

The remaining papers in this month's issue are: "Electro-diagnosis" by Dr. Edwin R. Bennett; and "A Case of Carcinoma of the Tongue" by Dr. Bayard Holmes. The growth extended, after two partial extirpations, to the alveolus. Partial excision of the lower jaw and partial excision of the tongue was performed with the result that no recurrence has taken place in three and one-half years.

---

THE CANADIAN PRACTITIONER

for July. Dr. R. W. Powell contributes an article on

**The Management of Abortion.**

When an abortion threatens, complete rest in bed on the back must be enjoined, and avoidance of all excitement; plain, easily-digested food allowed. Opium is to be given in full doses, and repeated sufficiently often to keep up its effect. Solid opium, morphia by the mouth or hypodermically, laudanum per rectum or in mixture, and also suppositories, may be used in such a case, at the discretion of the practitioner. Viburnum also has been highly lauded; pot. bromide is often very useful. These measures frequently avail to stave off the abortion, and if they do we should insist on the patient remaining in bed a week at least after the symptoms have entirely disappeared, and to resume her ordinary mode of life and avocations gradually, and with care to avoid all those causes which tend to a recurrence of the symptoms.

When the patient is actually aborting, he advocates the "let alone" policy, especially in primipara in whom the hemorrhage

is less likely to be excessive. If the pains are regular and good, nothing is demanded except rest in bed. He does not favor even vaginal douches in such a case, unless the locial discharge is offensive, in which case he prefers a weak solution of permanganate of potash in boiled water and a pad of sublimate jute to receive the discharges. If the pains are not good he advocates a dose of ergot.

In cases where the hemorrhage is excessive, and is coming away in clots, and especially where the patient is a multipara, the vaginal tampon, properly applied and tucked well around the cervix, is a useful means of assisting the process of dilatation. It likewise, by preventing the continuance of hemorrhage, allays the patient's fears. When the amniotic sac ruptures and the ovum is discharged minus the decidua, the hemorrhage is apt to be severe; to control this, he advocates the use of gallic acid and ergot, combined with a little opium or chloroform if the pains are severe and hard to bear. He has found the tampon useful in these cases in limiting the hemorrhage and promoting the dilatation of the cervix. The tampon should be changed every four to six hours according to the severity of the pains and the amount of hemorrhage. When the decidua is not discharged it must be removed and for this purpose the author prefers the index finger used as a curette. He does not advocate the immediate washing out of the uterus after an abortion. An offensive discharge, a chill and rise of temperature following an abortion would indicate that an intra-uterine douche was demanded. For this, the author prefers carbolic acid and permanganate of potash.

W. Lehmann, M. B. contributes a translation of an article on

**Lithopædion,**

by Dr. Gottschalk, of Berlin. Thirty years ago the patient had an extra-uterine pregnancy, the case being left to nature. Two years ago the mass slipped down into the pelvis and the patient suffered from pressure symptoms and became so emaciated that a section and removal of the mass was finally advised. The appendages of the right side were perfectly normal but the left ovary was entirely absent, the whole ovum lying in an ovarian sac. The author therefore believes that the case was originally one of ovarian pregnancy. The patient recovered perfectly.

# PERISCOPE.

## THERAPEUTICS.

### Caffeine-Chloral.

Chloral possesses the characteristic property of all aldehydes to combine with a variety of chemical substances, especially with those of a weak basic character, such as formamide, urea, cyanogen, etc., in which the physiological action of the respective compounds are more or less modified. The therapeutical advantages of some of these combinations are illustrated in the use of chloralamid, the compound of chloral with formamide, and it appears that a similar combination of chloral with caffeine may prove a valuable remedy in cases of constipation and in irritable conditions of the peripheric nervous system.

Caffeine-chloral has been recently employed with success by Ewald, who administered it subcutaneously dissolved in water, in single doses of three to five grains up to six to fourteen grains pro die. The injections were generally unaccompanied by the slightest pain, although individual patients complained of a slight burning sensation at the point of injection, which continued for about three hours.

Thirteen cases of constipation were treated: thin stools passed within three hours of injection of three to six grains caffeine-chloral in all cases in which the constipation was of three to six days' duration. In one instance an ounce of castor oil had been administered the day before without effect and copious irrigation had also been unsuccessful. Constipation appeared again in this case five days later, and six grains caffeine-cahloral were administered at intervals of two hours without previous dosage with castor oil, with like success.

In one case of gastric ectasis accompanied by severe paroxysms of pain in the neighborhood of the stomach, 5 grains caffeine-chloral were administered to combat the pain. The patient volunteered the information next morning that a thin stool passed a few hours after the injection and since that time the stools have been well formed and regular. Only one out of the thirteen cases of constipation withstood the remedy, and here irrigation had to be again resorted to.

Ewald also administered caffeine-chloral in eight cases of rheumatic difficulties, and in seven cases the pain and swelling of the joints was mitigated by injections of three to six grains pro die. In all these cases previous treatment with sodium salicylate for periods varying from two to seventeen days had been without effect upon the course of the complaint.

A complete disappearane of pain is reported in one case of ischia after a few days' treatment with injections of 3 grains daily, and considerable improvement was noticed in a case of supposed rheumatic pains in the testicles and hip-joints. The injections also proved serviceable in reducing the pain after lead poisoning.

In two cases of emphysia accompanied by violent attacks of asthma, which resisted

morphia, the rapid disappearance of complications after a single injection of three grains caffeine-chloral was remarkable. The asthmatic difficulties in a case of nephritis and myocarditis, were also diminished by injections, which further exerted a favorable influence on the chronic constipation.

As a result of his observations, Ewald is therefore in a position to state that the injections of caffeine-chloral have, besides a loosening action in cases of constipation, also a quieting and soothing influence upon the peripheric nervous system in irritable conditions. To what extent this action is due to the caffeine is at present doubtful, as experiments on animals have indicated that in the presence of the influence of chloral, the action of caffeine in less than toxic doses, is almost completely masked. It is also a well-known experience that in similar combinations of chloral with other bodies, such as urea and cyanogen, the specific action of the latter is almost completely annulled. Ewald therefore refrains from expressing a definite opinion as to the specific action of caffeine-chloral until further experiments have been made.

---

### Losophan.

Felix Descottes formulates the following conclusions: In the treatment of leg ulcers losophan acted quite as well as any of the medicaments employed in this condition. In primary lesions of a syphilitic character losophan had a very beneficial action and determined a rapid cicatrization of chancre though employed to the exclusion of the general constitutional treatment. The curative effects of losophan were especially manifested in simple chancre or soft chancre. Patients suffering from folliculitus and eczema, although not always completely cured under treatment by losophan, experienced in all cases a great amelioration of condition. In circumscribed lichen simplex losophan successfully cured the disagreeable and sometimes very painful pruritus which almost always accompanied this malady. In prurigo with obstinate pruritus the same beneficient result was obtained. Descottes employed losophan in much stronger mixtures than cited by other authors and never noted any irritation of the skin. He used eight per cent., ten per cent., and sometimes twenty per cent, ointments and solutions, and was successful in some conditions which had not heretofore responded promptly to losophan.

---

### Indications for the Administration of Chloralamid.

Dr. J. Hobart Egbert says: Having kept a record of more than one hundred cases in which chloralamid was administered for hypnotic and soporific effects with uniformly gratifying results, I believe that a review of some important indications for the exhibition of this remedy, as shown in these cases, will prove of practical value.

In preparing patients for operations, of even more importance than the orthodox laxative is the securing of refreshing sleep and, if possible, tranquillity of mind and freedom from depression. Nothing so prepares the human frame for the knife of the surgeon as deep, natural sleep on the eve of the operation. How, then, may this desideratum be secured? Opiates are at once excluded by the subsequent depression and digestive disturbances which they occasion, and many of the modern hypnotics are likewise barred on occount of their marked after-effects. With a view to obtaining calm, refreshing sleep prior to operations (and especially in operations upon the eye when no anæsthetic is employed), and otherwise preparing the minds of patients for the ordeal, we have latterly administered full doses of chloralamid at bed time for two or three nights before the operation. The results have been uniformly gratifying, not only in obviating much restlessness and discomposure at the time of operating, but also in securing immunity from surgical shock—symptoms of which are not infrequently observed after even trifling operations.

After every successful operation there comes a relaxation of the mental tension which has quietly, but firmly sustained the patient during the ordeal. This relaxation is naturally attended by a disturbance of nervous equilibrium, and as a result, unrest and insomnia are apt to ensue. When, in this event, insomnia is not dependent upon absolute physical pain, chloralamid is strongly indicated—not only because of its valuable sleep-producing qualities, but in virtue of its tonic action on central nervous cells and fibres, and *its power to relieve intra-cranial congestion.* This last-mentioned quality of chloralamid renders it an agent of superior value for post-operative administration in ophthalmic surgery. In these conditions we ordinarily prescribe chloralamid in extemporary elixir, using as a menstrum the Elixir Simplex of the U. S. Pharmacopœia.

Restlessness, insomnia and coma vigil are serious symptoms common to typhoid fever, and are indications for the exhibition of chloralamid. Since, in this disease, they are attended with much debility the remedy is best administered in brandy and water.

In the insomnia or fatiguing sleep of that debility of the nervous system commonly spoken of as nervous prostration or spinal irritation, and in all cases of nocturnal restlessness caused by excessive mental exertion or emotion, chloralamid has a wide field of usefulness and is early indicated. This drug is not contra-indicated by attendant debility; nor is its prolonged use likely to occasion either functional or organic disturbances, nor lessen its power to relieve.

Chorea is an indication for chloralamid. Not only should it be administered when muscular movements interfere with sleep, but systematically as curative of the disease. In the treatment of this affection it will sometimes be found advantageous to combine hyoscyamus with the chloralamid. Here is an eligible formula:

℞ Chloralamid..... ... ℥ss
In spts. vini gallici ℥i solve, tum adde
Tinct. hyoscyami..... ℥iv
Tinct. valerianae..... ℥i
Elixir simp..... q. s. ad ℥vi

M. Sig.: A teaspoonful four times a day.

In my own observation, attacks of chorea which have resisted morphia, have promptly yielded to ten grain doses of chloralamid.

In the insomia or disturbed sleep with unpleasant dreams which result from alcoholic, tobacco, and sexual excesses, chloralamid has a special field of usefulness. It should be given in full doses at bed-time, while mineral tonic and reconstructives should be administered throughout the day, and such a course, if accompanied by proper abstinence, will relieve the overtaxed economy,and prevent the otherwise inevitable spinal and cerebo-spinal sequelæ.

In mania and melancholia, chloralamid is superior to chloral and the bromides, not only for securing sleep but in contributing materially towards recovery—it being now a general opinion that cases of *acute* mania treated by these latter drugs are longer in recovering, and even more likely to result in dementia than those not so treated. On the other hand, chloralamid is well borne even in attacks of acute mania; and with imbeciles and demented persons in whom no active cerebral disease is progressing, it also affords excellent results.

From these observations may we not justly conclude that chloralamid is a practical, safe and efficient hypnotic—exercising, when properly administered, a salutary effect upon central nervous tissue; relieving abnormal intercranial congestion, and strengthening peripheral nerve fibres, without depressing the action of any vital organ or interfering with the normal bodily functions.—*Notes on New Review.*

## MEDICINE.

### Insanity Following Surgical Operations.

In order to present this subject says Dr. Lears in the *Boston Med. and Surg. Jour.* in form for discussion I have formulated the following propositions:

1. That the insanity following operations is identical in form with that which follows acute disease.

2. That it may follow the most trivial operations as well as the most serious; that after gyencological operations it possibly is, and after cataract operations it probably is more common that after other surgical procedures.

3. That the aggregate number of cases is greater in women than in men, but that this disproportion would be lessened and might even disappear if only such operations as are common to the two sexes be compared.

4. That the causes are those which induce perverted or exhausted cerebral nutrition, among which are shock, fear or anxiety before operation, the sudden relief from strain after it, sepsis, malnutrition and advanced age.

5. That it is impossible to say that iodoform or other antiseptics may not have been the cause of some cases, in the same manner that drugs taken by the mouth may lead to mental disturbance, but that these cases are probably very few in number.

6. That it unsually appears within the first two weeks and may even come on immediately after the operation; that if it develops after the lapse of two or three months it is probably the result of other causes or is at best but indirectly connected with the operation.

7. That the prognosis is not particularly good, but 60 or 70 per cent. of the cases at most recovering; that recovery is more common in men than women, and when it occurs, takes place usually within a few months, but that the outlook is not absolutely unfavorable even if it continues for a longer period.

8. That hereditary influences are of comparatively slight importance while a condition of previous mental or nervous instability is a decided factor in inducing its appearance.

9. That when a patient shows a marked tendency to insanity, or when nental symptoms are already present, an operation is attended with much danger in this respect and great responsibility rests upon the surgeon who advises it.

10. That the progress of the wound is not influenced by the onset of insanity *per se.*

### Tests of Death.

Dr. Edwin Howard describes a case in the *Lancet*, June 10th, in which the question whether death had occurred was entered into at length, because of the lifelike appearance of the body, and a history of a previous death-like trance. With Sir Benjamin Ward Richardson the following ten tests were undertaken, two of which argued for, the other eight against, the presence of life. The paper is intended to show that the "diaphanous test" (No. 10) is unreliable, as in this case the fact of death was subsequently proved by waiting for decomposition. The list of tests is instructive, and may at any time be useful to a medical man.

(1) Heart sounds and motion entirely absent, together with all pulse movement. (2) Respiratory sounds and movements entirely absent. (3) Temperature of the body taken from the mouth the same as that of the surrounding air in the room, 62° F. (4) A bright needle plunged into the body of the biceps muscle (Cloquet's needle test) and left there shows on withdrawal no sign of oxidation. (5) Intermittent shocks of electricity at different tensions passed by needles into various muscles and groups of muscle give no indication whatever of irritability. (6) The fillet test applied to the veins of the arm (Richardson's test) causes no filling of veins on the distal side of the fillet. (7) The opening of a vein to ascertain whether the blood has undergone coagulation shows that the blood was still fluid. (8) The subcutaneous injection of ammonia (Monte Verdi's test) causes the dirty brown stain indicative of dissolution.

(9) On making careful movements of the joints of the extremities, of the lower jaw and of the occipito-frontalis rigor mortis is found in several parts.

Thus of these nine tests eight distinctly declared that death was absolute; the exception, the fluidity of the blood, being a phenomenon quite compatible with blood preter-naturally fluid and at a low temperature, even though death had occurred.

There now remained the diaphanous test (10), which was carried out by the aid of a powerful reflector lamp, the scarlet line of light between the fingers was as distinct as it was in living hands subjected to the same experiment.

### Epileptic Neuralgia of the Face.

Dr. Fere reports a case in which neuralgia of the face is associated with epilepsy. This has been observed before; Trousseau declared it to be simply coincident. The absence of hereditary taint, of intellectual disturbances, and of simultaneous occurence of both affections, seemed to speak for the correctness of Trousseau's idea. In the following case, however, there is no absence of the foregoing symptoms, and what constitutes a further proof is that a cure of both diseases was brought about by the same remedy. The patient was a man 42 years of age, in whose family, on the maternal side, there was a decided hereditary taint. He had for six years been suffering from neuralgia of the face. At first the attacks occurred not oftener than every fourteeen days, and were confined to the left side. They began on the chin and at the same time the skin became red, followed by the development of confluent maculæ. In the course of years these attacks became more and more painful and frequently (as many as 20 in one day). At the same time spasms at the side of the eyelids accompanying the pains showed themsleves. Finally, after a number of medicines had been tried without benefit, epileptic attacks developed. By means of large doses of bromide of potash (7—10 grammes *per diem*) the epilepsy and neuralgia were cured within a few months, which would seem to show that the two affections had a common cause. —*Central Med.*

## SURGERY.

### Digital Compression in the Vomiting of Anæsthesia.

Dr. Bernard Joos describes a method for the control of the hiccough and vomiting during anæsthesia, which he has found successful for several years. It consists in digital compression of the phrenic and vagus nerve against the sternal end of the clavicle. His method is as follows: As soon as singultus or vomiting begins, the etherizer presses the last phalanx of the left thumb firmly over the sternal end of the clavicle, the body of the thumb being parallel with the clavicle and the hand resting on the chest. The pressure is made with the radial side of the thumb. The vomiting stops at once, as a rule. If needed, or more convenient, the pressure may be made on the right side. Pressure is continued for a few moments to prevent a return of the vomiting. He recommends the trial of this method in cases of sea-sickness.—*Bost. Med. and Surg. Jour.*

## NEWS AND MISCELLANY.

### Pan-American Medical Congress.

Committee of Arrangements, Washington, D. C.—Samuel S. Adams, M. D., Chairman; J. R. Wellington, M. D., Secretary; G. L. Magruder, M. D., Treasurer.

Executive Committee.—Dr. Samuel S. Adams, Chairmam; Surgeon-Generals Geo. M. Sternberg, U. S. A.; J. Rufus Tryon, U. S. N.; Walter Wyman, U. S. M. H. S.; Drs. S. C. Busey, G. Wythe Cook, Carl H. A. Kleinschmidt, H. L. E. Johnson, Llewellyn Eliot, H. H. Barker, C. W. Richardson, W. Sinclair Bowen, Geo. S. Ober, G. L. Magruder, J. R. Wellington, and John R. Walton, D. D. S.

SUB-COMMITTEES.

Reception.—Dr. S. C. Busey, Chairman; Surgeon-Generals Geo. M. Sternberg, U.S.A.; J. Rufus Tryon, U. S. N.; Walter Wyman, U. S. M. H. S.; Drs. J. Ford Thompson, Charles Hagner, Louis Mackall, J. Taber Johnson, T. Morris Murray, G. Byrd Harrison, and Jos. H. Bryan.

Entertainments.—Dr. G. Wythe Cook, Chairman; Drs. G. N. Acker and Thos. E. McArdle.

Registration.—Dr. Carl H. A. Kleinschmidt, Chairman; Drs. John S. McLain and Johnson Eliot.

Railroads.—Dr. H. L. E. Johnson, Chairman; Drs. E. L. Tompkins and J. Foster Scott.

Printing.—Dr. Llewellyn Eliot, Chairman; Drs. Thomas N. Vincent and F. B. Bishop.

Halls and Exhibits.—Dr. H. H. Barker, Chairman; Dr. J. T. Winter and C. M. Buchanan.

Ways and Means.—Dr. C. W. Richardson, Chairman; Drs. John Van Rensselaer, Wm. Dillenback, Henry B. Deale, and Wm. Compton.

Information.—Dr. W. Sinclair Bowen, Chairman; Drs. E. Oliver Belt and F. S. Nash.

Hotels.—Dr. Geo. S. Ober, Chairman; Drs. Wm. E. Handy and D. O. Leech.

Dr. Ernest Hart, Editor of the *British Medical Journal*, and Prof. Dr. Czerny, of Heidelberg, will be among the distinguished guests of the Pan-American Medical Congress. The latter is booked for the Pan-American Excursion to Rome by the "*Werra.*"

OFFICIAL DELEGATES TO THE PAN-AMERICAN MEDICAL CONGRESS.

Practically all of the Governments have appointed official delegates to the Congress

in response to the invitation by the President of the United States. The U. S. Government will be represented by six delegates. The larger cities of all the Latin-American Countries have appointed delegates to participate in the proceedings of the Sections of Hygiene, Climatology, and Demography, and on Marine Hygiene and Quarantine, and similar appointments will be made by the cities of the United States. Seventy-six similar delegates have so far been appointed by the Governors of States in the United States. A large number of delegates have been chosen by the medical colleges of the United States and other American Countries to attend the Section on Medical Pedagogics, under the Presidency of Professor J. Collins Warren, of Boston.

---

At the last meeting of the Ohio State Medical Society, the following officers were elected: President, N. P. Dandridge, M. D., Cincinnati; 1st Vice Pres., F. C. Larimore, M. D., Mt.Vernon; 2nd Vice Pres., Wm. Caldwell, M. D., Fremont; 3rd Vice Pres., W. T. Corlett, M. D., Cleveland; 4th Vice Pres., L. S. McCurdy, M. D., Dennison; Secretary, Thos. Hubbard, M. D., Toledo; Asst. Secy., Chas. Græfe, M. D., Sandusky; Treasurer,J. A. Duncan, M. D., Toledo.

## ARMY AND NAVY.

U. S. ARMY FROM JULY 16, 1893, TO JULY 29, 1893.

Captain Leonard Wood, Assistant Surgeon is relieved from duty at Presido of San Franciso, Cal. and ordered to Fort McPherson, Georgia, for duty.

Captain Louis W. Crampton, Assistant Surgeon, is relieved from duty at Fort Spokane, Washington, and from temporary duty at Hdgrs, Dept of the Colorado, and ordered to Baltimore, Md. as Attending Surgeon and Examiner of Recruits, relieving Capt. Charles B. Ewing, Assistant Surgeon.

1st Lieut. James D. Glennan, Assistant Surgeon, ordered to report to the president of the examining board for examination for promotion.

Major Peter J. A. Cleary, Surgeon, granted leave of absence for four months on Surgeon's certificate of disability.

1st Lieut. A. E. Bradley, Assistant Surgeon, ordered to report to Lieut. Col. Sallas Bache, deputy surgeon general, president of examining board at Omaha, Neb., for examination for promotion to grade of Captain.

1st Lieut. J. T. Clarke, assistant surgeon, will on the abandonment of Camp Poplar River, Mont. proceed to Fort Sully, S. S. for temporary duty, and on return 1st Lieut. Bradley proceed to and take station at Fort Omaha, Nebraska.

Leave of absence for one month, to take effect between the 15th and 30th instant, is granted Major Calvin DeWitt, surgeon U. S. Army.

Captain Richard W. Johns, Assistant Surgeon, will report on or before August 6, 1893. to the commanding office Fort McHenry Maryland, for temporary duty at that post during the absence of Captain Charles B. Ewing, Assistant Surgeon.

Leave of absence for one month, to take effect when his services can be spared at Fort Wingate, N. Mexico, is granted Major Louis M. Maus, Surgeon U. S. Army.

Leave of absence for two months, to take effect, on or about September 15, 1893, with permission to apply for an extension of one month, is granted 1st Lieutenant Benjamin L. Ten Eyck, Assistant Surgeon U. S. Army.

Captain William B. Davis, Assistant Surgeon, is releived from duty at Fort Sam Houston, Texas, and ordered to Fort Brown, Texas, for duty, relieving Captain George A. Torney, Assistant Surgeon.

Captain Torney upon being relieved, by Captain Davis, will proceed to and take station at Philadelphia, Pennsylvania, as Attending Surgeon and Examiner of Recruits at that place.

**Half Rate Excursions to the World's Fair via Washington and the B. & O. R. R.**

The Baltimore and Ohio R. R. will run a series of special excursions from New York to the World's Fair at rate of $17.00 for the round trip. The trains will consist of first-class day coaches equipped with labatories and toilet conveniences. The trains will start from Jersey Central Station, foot of Liberty Street, New York, at 8.30 A. M., Aug. 5th, 9th and 15th, and reach Chicago at 4.30 P. M. the following day. Tickets will be valid for outward journey only on the special trains, but will be good returning from Chicago in day coaches on any regular train within 10 days, including day of sale. Stops will be made for meals at the dining stations on the line. A Tourist Agent and a train porter will accompany each train to look after the comfort of passengers. Tickets will also be sold for these trains at the Jersey Central offices in Newark, Elizabeth, Plainfield, Bound Brook and Somerville. New York offices 172, 415 and 1140 Broadway, and Station foot of Liberty Street.

---

**Picturesque Route to the Fair.**

No other line offers the variety of scenic interest between New York and Chicago that is enjoyed by World's Fair tourists via the Baltimore and Ohio Railroad. Passing through Philadelphia, Baltimore, Washington, the capital of the nation, and by way of Harper's Ferry and the historic Potomac Valley to the Allegheny mountains, which are crossed at an elevation of 3,000 feet above the sea, the traveler sees the arena of the activity of the nation as well as the principal historical features and scenic wonders of the East. Low rates.

# FRACTURES OF PATELLA, WITH REPORT OF CASE TREATED BY SUTERING.

WILLIAM MACKIE, M. A., M. D.†

In considering the subject of fractures of the patella, I propose to first direct attention to some points in the anatomy of the bone, then the etiology, pathology, symptoms, prognosis, causes of non-union, treatment, and conclude by giving the history of a case which came under my personal observation.

*Anatomy.*—The general outline of the patella is triangular. To the apex and underlying rough surface is attached the ligamentum patella; and to the margins the tendinous expansion of the vasti. The upper border is oblique in direction, the outer edge being about one third of an inch higher than the inner. It is marked by a transverse groove into which anteriorly, the tendon of the quadriceps extensor is inserted and continued over the front of the bone to become continuous with the ligamentum patellæ.

Until pointed out by MacEwan,[1] this aponeurosis in front of the bone was supposed to be either wanting, or of such limited extent as to be unworthy of consideration. To demonstrate its existence and character, he divided longitudinally the quadriceps extensor tendon, patella and ligamentum patellæ, then sawed the patella partly through in a transverse direction from the articular surface so as to admit of easy fracture of the bone. After breaking the bone, the lower fragment was torn from its ligamentous and aponeurotic attachments, leaving them exposed.

In young children he found the ligamentous structures in front of the bone were represented by a thin film, in many places scarcely distinguishable from the cartilage. In advanced life they were attenuated especially over the center of the patella.

In six instances ranging from fourteen to forty-five years of age, (the period during which fractures of the patella occur), the aponeurotic structures ran in a distinct band over the front of the patella continously from the tendon of the quadriceps to the ligamentum patellæ. The antero-posterior thickness of this layer ranged from one thirty-second to one sixteenth of an inch. The bulk of these fibres were longitudinal in direction, many continuous from tendon to ligament; a few were oblique.

The patella is the analogue of the olecranon, and serves to increase the power of the extensor muscles by causing them to act on the knee at a greater angle. With the limb extended and the quadriceps inactive, it is freely movable from side to side and upward and downward, and does not become fixed until the knee is flexed to an angle of 130°. This great mobility is difficult to overcome in the treatment of fractures.

*Etiology.*—Fractures of the patella may be the result of either direct or indirect violence. The former is due to the application of the fracturing force to the bone through the medium of the over-lying soft tissues, with or without wound, and the latter to the violent contraction of the

† Surgeon Milwaukee Hospital, Milwaukee, Wis.

quadriceps extensor muscle in extraordinary efforts made to prevent the body from falling, in lifting heavy weights, in assuming the erect position from kneeling, or any other condition in which the muscle is brought vigorously and suddenly into action. Direct traction is also said to produce it, and in proof of this Stimson[2] instances a case recorded by Garreau, where the second fracture occurred in the upper fragment after ligamentous union of the primary fracture with 4cm. separation. Clinically those the result of indirect violence are the most common. Of 127 cases observed by Hamilton, 107 were assigned to this cause. The mechanism of those resulting from direct violence is simple, that of the indirect is more complex. It is thus described by MacEwan: "The sudden development of the full retractile force of the powerful quadriceps causes the patella to be jerked upward, relatively to the femur, beyond the position where it usually lies supported laterally by the femoral patellar surface. The patella being held below by the powerful ligamentum patellæ, rests on the apex of its posterior vertical edge, which thus becomes the point upon which is developed the greatest energy of the two opposing forces; that of the contractile power of the quadriceps extensor, and the weight of the body on the other." That is, the patella becomes converted into a lever, the fulcrum being the apex of the vertical ridge resting on the condyle of the femur; the active force, the contraction of the quadriceps extensor attached to upper border of the bone; and the passive, the resistance of the ligamentum patellæ. The bone gives way; the contraction continuing, the fragments separate and the aponeurotic coverings being more elastic, rupture at a lower level than the line of fracture. This laceration may extend into the capsule of the joint and the præ-patellar bursa. Many cases attributed to direct violence are doubtless the result of indirect, because if the patient fall and strike upon the knee, he naturally assigns the fall as the cause.

Forcible flexion of an anchylosed knee where the patella is adherent to the femur may produce fracture. Cases are recorded by Desault, Valette, and Marcy, where both patellæ have been simultaneously fractured.

*Pathology.*—1. Direct.—The superficial soft tissues will be found contused or lacerated. The line or lines of fracture may assume any direction, depending upon the point of application and character of the fracturing force—seldom, however, is it transverse. Paul Swain[3] records a case of the latter in a girl five years of age, who fell on some sharp shingle on the beach and divided the patella transversely as if the section had been made with a knife. The præ-patellar aponeurosis, the fibres of which we have already seen are mostly vertical in direction, is not lacerated to any great extent, hence there is less separation of fragments and greater tendency to bony union.

2. Indirect.—The line of fracture is transverse or slightly oblique, and at or just below the middle of the bone. The degree of separation of the fragments is dependent upon the condition and proportionate to the extent of laceration of the præ-patellar aponeurosis. If the aponeurosis remains intact or only slightly torn there will be little or no separation of the fragments and bony union will result.

When laceration occurs bony union without resort to operative measures is the exception. A satisfactory explanation of this was first given by MacEwan[4] in 1883. As already pointed out the laceration of the aponeurosis occurs at a lower level than the line of fracture and, the direction of the fibres being longitudinal, the free end presents a shreddy appearance. On the occurrence of fracture, the retraction of the quadriceps extensor tendon, from its manner of insertion into the upper fragment, tilts it forward so that the fractured surface presents anteriorly and those shreds instead of remaining free, become firmly entangled amongst, and mechanically intimate with the projecting spiculæ on the fractured surface, so that it is necessary to remove a thin section of the bone to free them. Flexion of the knee which follows the accident increases this tilting and entanglement. This condition of parts had been verified in cases of recent fractures operated on, and confirmed post-mortem by Rushmore of Brooklyn, in two cases where he found the periosteum lacerated at a lower level than the line of fracture and folded over the upper fragment like an apron. Riedel[5] has also found this condition post-mortem, and calls attention to rupture of the upper recess of the synovial cavity. Whether this occurs at the time

or follows as the result of elastic compression applied, is uncertain. Experimentally he ascertained that with 200 c. c. of fluid in the joint cavity, the upper recess gave way under 25-30cms. pressure of mercury. Fowler[6] believes that this rupture may be produced by the same violence which fractured the patella.

Hæmarthrosis is always present but seldom to any great extent. Geo. R. Fowler[7] records a case of recurring hemorrhage. Soon after accident the joint became distended with blood. Under evaporating lotions and compression the hemorrhage was arrested and on the seventh day a plaster of Paris splint was applied. Three days later it was necessary to remove the splint on account of recurrence of the hemorrhage. Aspiration was tried but failed; cold compresses were again applied. On the fifteenth day after injury, the pulse and temperature rose and the tension of the joint increased. The joint was opened, a half-pint of coagulated blood turned out and the source of hemorrhage found to be the internal articular artery which had been torn across by the giving way of the accessory band of ligamentous tissue extending from the vastus internus muscle to the head of the tibia. This band was ruptured about one and a half centimeters below the line of fracture. Hemorrhage and effusion into the joint produces further separation of fragments by distension of the joint cavity.

*Symptoms.*—As a rule the diagnosis is easy. There is a history of trauma, or sudden snap in the knee with or without fall, pain, swelling and diminished or absolute loss of power of extension. In the direct form there is evidence of injury to soft tissues; the separation of the fragments is not marked because of a more or less intact condition of the aponeurosis; crepitus can be elicited, although not in every case. Morris[8] records the case of a girl who struck her knee against a chair, where careful examination failed to detect fracture. She continued to walk around, up and down stairs, with considerable pain and swelling in joint. Two days later a posterior splint was applied and on subsidence of the effusion, crepitus could be detected by fixing the patella between finger and thumb of one hand and carefully pressing with the finger of the other around the margin of the patella. An oblique fracture without separation of the fragments was thus diagnosed. Morris strongly recommends this method of examination in obscure cases.

A source of error, as pointed out by Tillaux, is an effusion of blood into præpatellar bursa which may give a sense of crepitation, and the blood clots may be mistaken for fragments.

The degree of separation in the indirect form depends upon the extent of the laceration of the aponeurosis. Morris has shown in the cadaver after subcutaneous fracture of the patella by a chisel, that when separation induced by bending the knee reaches half an inch, the aponeurosis gives way. Hamilton holds that separation of one inch indicates laceration of the aponeurosis. The extent of separation cannot be taken as an absolute criterion of the condition of the soft tissues. Upon this also depends the degree of loss of function. Tresort[8] records the case of a robust man who continued at work for three weeks, then suspected fracture from the swollen condition of the knee and on seeking advice two months later, a transverse fracture between the middle and lower thirds could be easily detected. MacEwan[1] also records the case of a student who fractured his patella while playing foot ball, who could walk without much difficulty or pain but with a sense of crepitation in the joint. Where the separation is well marked, a groove in the skin indicates the site of fracture. This can be deepened by flexing the knee —a proceeding always to be avoided because it increases the extent of laceration sustained by the soft tissues and the entanglement of lacerated fibrous tissue in rough fractured surfaces. It is the exception to be able to obtain crepitus in the indirect form unless the aponeurosis is intact. Crepitus may be found with laceration when the fragments are approximated. This occurs between the posterior edges of the fragments and is no indication of the absence of intervening soft tissues. The effused blood also deadens crepitation.

*Prognosis.*—Prior to the introduction of operative treatment, ligamentous union has been the rule, and when such anatomical defect exists there must remain more or less functional disability. Where the continuity of the bone has been restored by bony union the result is different. Then only can organic changes in

the structures entering into the formation of the joint, or intrinsic injury to the quadriceps extensor muscle at the time of the accident, diminish the former strength and usefulness of the limb. With ligamentous union there remains weakness of the limb through loss of extensor power. This is evidenced by inability to bring the foot forward or to elevate the heel from the horizontal position of the knee extended. On slight flexion of the knee this can be accomplished. The shortened quadriceps extensor is put on the stretch and can then contract, or the fascial expansion of the vasti extending over the capsule of the knee laterally may act on the lower fragment. The latter applies more especially to cases where the upper fragment has become adherent to the femur and consequently cannot be acted on by the muscle, and where in flexion of the knee the inter-space between the fragments is increased. Bergmann[9] (1887), ascribes this diminished power of extension more to trauma sustained by the muscle than to incomplete consolidation. The degree of separation is not proportionate to the loss of power. Stimson[10] records a case with four and one-half inches of separation when the limb was extended, and although there was no power of active extension, except to a slight degree through the aponeurotic attachments in the position of nearly complete extension, four years after the injury the patient walked easily and securely; also Bryant[11] notes where with four inches interval, a man could ascend a ladder as well as ever.

*Causes of Non-union.*—The following causes have been assigned for non-union: separation of the fragments by the contraction of extensor muscle; effusion into the cavity of the joint; deficient blood supply, and the inter-position of the præ-patellar aponeurosis.

1. Separation of fragments by the contraction of the extensor muscle. The upper fragment is retracted by the muscle, which however soon assumes the condition of rest. If no attempts were made to bring the fragments into apposition this could be accepted as a cause, but this muscular contraction can be overcome in recent cases by pressure downward with the fingers. This MacEwan found to be the case where the parts were exposed shortly after the accident. In old cases with long standing ligamentous union the muscle is permanently contracted and here arises the difficulty of bringing the fragments into close apposition.

2. Effusion into the cavity of the joint. This effusion is a mixture of blood and synovial fluid and is at times well marked. Distension of the joint cavity may for a time further displace the fragments by forward pressure but, as absorption rapidly ensues, its effect can only be of temporary significance. Blood clot may form on the fractured surfaces and remain unabsorbed for a time. This condition exists in all forms of fractures, and can with equal truth apply to non-union in other localities. It does not however, and even an encrustation of blood on the surface of the fragments where accurate coaptation is not obtainable, may be of service in forming a transient medium in which the osteoblasts can obtain support and develop.

3. Deficient blood supply. The vascularity of the patella has been demonstrated fully by injection of its blood vessels and further by the parenchymatous oozing after fracture occurs, and of the character and extent of this we have ocular proof in operations on the knee joint, such as a resection where section of the patella is made. If this be a sufficient cause it should apply with equal force to other than transverse fractures, but the reverse holds that bony union generally follows in fractures resulting from direct violence.

4. Inter-position of the præ-patellar aponeurosis. This has already been referred to in the pathology, and all must admit this as a potent cause of non-union.

*Treatment.*—This consists in obtaining and maintaining accurate coaptation of the fragments accomplished either by mediate or immediate means of fixation, and the expectant plan or treatment by massage. The latter method was introduced by Tilamus of Amsterdam, who, at the French Congress of Surgeons in 1885, reported six cases with good results. On the first day he applies elastic compression and cold compresses to the joint, with elevation of the limb; on the second, while the fragments are held in apposition by the fingers, the thigh is thoroughly massaged. This is repeated every twelve hours. On the fourth day, passive and active movements of the joint are practiced, and on the eight day, the patient is allowed to get up. In the six cases the

patients could walk by the fourteenth day and, in spite of movement, the distance between the fragments became daily less. He believes that rapid union and the early employment of motion are the best means to prevent shrinkage of the capsule, false anchylosis and muscular atrophy. Ligamentous union of considerable length occurred in every case. His results bear a very favorable comparison with cases treated by long continued fixation and confinement. Another interesting case in this connection is recorded by Flower.[12] It is that of a milkman, who continued at his work during the whole period of treatment. A posterior splint of light hoop-iron was shaped to the limb and held in place by straps and buckles. Rollers so placed as to secure the fragments in as favorable a position as possible, were held in place by adhesive plaster. The splint was discarded in about five weeks, and the result was as good as that which followsany non-operative method of treatment.

The variety and complexity of the means proposed for the mediate fixation of the fragments is a true indication of the difficulties to be overcome, and the general principle underlying all is fixation of the limb in the extended position, the bringing of the fragments into apposition and retaining them by direct pressure. The small size and mobility of the fragments render this a difficult task. Pressure exerted on the upper fragment, either by circular ring or oblique bandage of whatever character, compresses it against the femur, thus depressing the tendon of the quadriceps extensor, which, being inserted into the anterior surface of the bone, causes the fractured surface to assume an angle with the long axis of the limb. The same applies to the lower fragment but in a less marked degree. The fractured surfaces cannot thus be brought into accurate apposition throughout. They form, as it were, a V-shaped gutter, their posterior margins being in contact and the anterior separated. Further, the upper margin of the patella is not horizontal, the outer end being at a higher level than the inner, hence the coaptating pressure will act with greatest effect on the outer half, so that externally the fractured surfaces may be in apposition while the inner are apart and the upper fragment is rotated somewhat outward. This explains the condition found in ligamentous union that the bond of union is always longest on the inner side. Another danger of this backward pressure of the upper fragment is the formation of adhesions between the femur and patella. Retentive apparatus should never be applied immediately after the accident; if done then it would increase the tendency of the fragments to tilt forward and the constricting effect would tend to increase the intra-articular effusion.

Time should be allowed for the subsidence of swelling by absorption. This is best kept within bounds by the application of ice. Elastic compression by a rubber bandage is recommended by some, but this must be used with the greatest caution because, as Riedel pointed out, rupture of the upper synovial sac may be produced. Compression by wrapping the joint in a large layer of cotton-wool and applying a flannel bandage is much safer and answers the same purpose. To overcome this swelling, Schede, in 1872, aspirated the joint and irrigated with 3 per cent. solution of carbolic acid. He then coaptated the fragments as closely as possible with adhesive strips and applied a plaster-of-Paris dressing. This was renewed at the end of a week, the fragments being brought into closer apposition with the same dressing for fixation. If neccessary it was again renewed in a week. By this means he obtained osseous union in three cases and firm ligamentous union in two.

For a full review of the mechanical means that have been employed in the treatment of the fracture, I would refer you to a paper by Dr. Charles F. Stillman, published in the Journal of the American Medical Association, February 28th, 1891, entitled "A Historical Record of the Devices used in the Mechanical Treatment of Simple Fracture of the Patella."

The immediate fixation of the fragments is accomplished by hooks or by some form of suture. Malgaigne's hooks were introduced about 1840. They were soon discarded on account of the disastrous results following their use in preantiseptic times. In later years they have again come into use. Morton,[13] in 1882, expresses himself as greatly in favor of a modified form of Malgaigne's hooks where the space between the hooks could be varied. He applies them about the fourth day and removes them in sixteen or seven-

teen days. He, in 1873, had a case in which the original separation was two inches and where after repair, it was impossible to detect which patella had been fractured. Treves,[14] in 1886, had the hooks made in two parts, introduced the points firmly into the bone through four small openings made in the skin by a tenotome, brought the segments together and screwed the fragments into close apposition. The hooks were allowed to remain *in situ* six weeks. The same author,[15] in 1892, exposes the fragments, clears away all intervening fibrous tissue and applies the hooks in the same manner. Levis modified them by dividing them into two independent pairs, so that the points could be inserted wherever desired.

The fixation of the points by suturing was proposed by Severino in the sixteenth century, and was first put into practice by Rhea Barton in 1834, and later by McClellan in 1838, (Dennis);[16] again by Cooper, of San Francisco, in 1861, and since, by Logan and Gunn, of Chicago, (Jalaguier)[17]. Of these five operations, two terminated fatally and of those that recovered nothing definitely is known. The operation was re-introduced by Cameron, of Glasgow, in 1877, who sutured the patella with wire in a case of ruptured ligamentous union. Lister,[18] in the fall of the same year, operated in a similar manner fourteen days after the accident. In 1879, Bell reported to the Medical Society of London, a case where he wired the fragments sixth months after fracture, and Rose two cases on the nineteenth day. This free opening of the knee joint and suturing of the fragments, generally known as Lister's operation, did not meet with general approval and surgeons looked for some less hazardous means of accomplishing the same end.

Kocker, in 1880, passed a silver wire vertically through the joint behind the fragments and twisted the ends over a piece of gauze in front of the bone, tightening it daily until the fragments came together. He only obtained diminished separation with fibrous union. Barker,[19] in 1892, made a similar operation subcutaneously and at the same time evacuated the blood from the joint.

He introduces a narrow bladed knife into the joint through the middle of the ligamentum patellæ, makes an incision downward for two-thirds of an inch, through which he expresses the fluid contents of the joint cavity (operating within twelve hours of the accident), introduces a needle fixed in a handle, passes it behind the patella upwards through the middle of the quadriceps extensor tendon and cuts down on it when it reaches the skin. The needle is protruded, threaded with silk and withdrawn, it is again introduced through the lower incision, passed in front of the fragments and out through the same incision above, threaded with the free end of the silk and withdrawn. In making the incisions care is taken that they extend down to the bone so that no fibrous tissue may intervene between the suture and the bone. The ends of the suture are drawn tight and at the same time, the fragments are forced into apposition and rubbed by lateral and anteroposterior movements against each other, until it is felt that any blood-clot or other material is dislodged. The suture is then tied on the lower border of the patella and the ends cut short and buried. An ice-bag is applied and the limb placed in a splint for eight or ten days, when it is removed and the patient is allowed to get up with a splint on, and to walk at the end of five weeks. He reports four cases treated thus, with bony union. Volkman passed a silk suture through the tendon of the quadriceps and the ligamentum patellæ and tied the ends in front of the joint, over a roll of gauze. Stimson[20] accomplishes the same thing subcutaneously. He makes four small incisions at the angles of the patella, introduces a Hagedorn needle threaded with silk, passes it subcutaneously through the ligamentum patellæ and brings it out at the corresponding incision on the other side. He then reintroduces it at the point of exit, passes it along the side of the patella and out through the opening above, and so on until the silk has surrounded the whole bone. The fragments are drawn together by tenacula inserted above and below, the suture pulled tight and tied and the incisions closed by catgut suture. By this method the joint is not invaded. He reports twenty-five successful cases. Mayo Robson passes steel pins through the tendon, approximates the fragments and retains them by a figure-of-8 suture round their projecting ends. Marshall, of University College, in 1878, transfixed the two fragments with steel rods and brought

them into contact by tying the ends of these rods together on either side, outside the skin. This procedure was brought forward by Lund, of Manchester, in 1882, and by Myles, in 1889. Ceni (Genoa) after preliminary aspirative irrigation of the joint, brings the fragments together by the figure-of-8 sutures of silver wire passed obliquely through the substance of the patella and round its upper and lower margins. Aiken proposes to pass a silver wire suture vertically through the boneand skin.

In the history of the following case will be described the operation by athrotomy and suturing. The majority of surgeons prefer the longitudinal incision; Phelps adopts the transverse; following the sulcus between the fragments. As to the time for operating in recent cases, it is better to wait until all danger of inflammatory symptoms from the trauma is past.

C. W., 22 years of age, on April 7th, 1891, sustained a transverse fracture of the right patella while endeavoring to prevent three horses hitched to a tread mill from running away. In doing this he states that he threw his right leg forward, braced himself on it, felt something give way in the knee, fell, then got up and walked about eight rods to a house. A physician was called, who found a transverse fracture below the middle of the bone. Cold water dressings were applied for ten days and then plaster-of-Paris fixation for six weeks; crutches used thereafter until the end of June, walking was attempted and on the third day re-fracture occured. The patient was admitted into the Milwaukee Hospital July 2nd, 1891. On examination there was found considerable effusion into the joint, discoloration of overlying soft tissues and separation of fragments about one inch. It was impossible to bring the fragments into apposition. A posterior splint was applied with moist antiseptic compresses over knee, for twelve days. By this time discoloration had completely gone and to a great extent the effusion into the joint.

On July 15th, 1891, under strict antiseptic precautions, the joint was opened by longitudinal incision in the middle line of the limb. On exposing the seat of fracture and separating the fragments, a quantity of bloody synovial fluid escaped from the joint cavity. Both fragments were freely movable and the interspace, one-half inches in the extended position, was occupied by a band of dense fibrous tissue which had given way close to the lower fragment. The fractured surface of the upper fragment was directed forward and that of the lower upward. There was laceration of the capsule laterally to the extent of one inch. There was no attempt at bony union. A small piece of sterilized gauze was placed under the fragments to guard against injury to and soiling of the joint cavity. Thin sections of bone with the attached ligamentous band were removed. Three holes extending down to but not perforating the articular cartilage, were drilled obliquely, at corresponding points in either fragment and sutures of silk-worm gut introduced. When these sutures were drawn tight the fragments were still half-an-inch apart. To overcome this, the limb was elevated to the perpendicular, i. e., flexed at right angles to the trunk and firm downward compression made on the extensor muscles. This brought the fragments into accurate coaptation. The silk-worm gut sutures were tied, ends cut short, aponeurotic coverings of the bones and capsules sutured with cat-gut, and the external incisions with silk. A copious antiseptic dressing was applied, the limb placed in a long posterior splint with a foot piece and over all a plaster-of-Paris dressing from toes to groin.

The further progress of the case was uneventful. The limb was maintained at right angles to the body for ten days and kept elevated for two weeks longer. The dressings were changed on the eighteenth day, when the incision was found united thoroughout and to all appearance commencing union between the fragments. The limb was kept in plaster-of-Paris for four weeks longer, all dressing discarded and the patient was allowed to walk with the aid of crutches. On Sept. 16th, he left the hospital with the patella firmly united; able to flex the knee to a right angle and to walk without the aid of a crutch. When last seen, one year after, the continuity any outline of the patella were normal and the functions of the limb completely restored.

For suturing material silver wire has been most generally employed—platinum wire and catgut have also been used. MacEwen recommends that the wire should be extracted after it has served its purpose; others leave it *in situ,* hammering the ends into the bone. Partia necrosis of the fragments have followed its

use, but the rule is that it causes no disturbance.

Chaput[22] reports successful cases by silk suturing of the fibro-periosteal covering of the bone. If continued success follows this method, and, unless it be the difference in degree of the trauma, there is no reason why it should not, as this proceeding suffices in cases where the patella is divided in re-section of the knee, a decided advance has been made in the treatment of this fracture. In old cases, to overcome the difficulty of approximating the fragments, various expedients have been resorted to. MacEwan[24] recommends a row of V-shaped incisions in the tendon of the quadriceps above the patella. This avoids complete section and gains considerable length.

Stankiewicz,[23] in a case of refracture after seventeen weeks, had to avoid the tendon of the quadriceps and ligamentum patellæ so as to suture the fragments, which united firmly with anchylosis and the patient walked well without assistance after three months.

R. Park[24] divided the tendon of the quadriceps in a case of long ligamentous union with good result. The danger of section of the quadriceps tendon is necrosis of the upper fragment. Von Bergmann[25] records such an occurrence. He chisels off obliquely the tuberosity of the tibia and fixes it below the knee joint.

The results obtained by mediate approximation are decidedly bad and unsatisfactory when compared with those following immediate fixation, and the question should all recent cases, and old ones entailing functional disability, be submitted to operative treatment, must be given an affirmative answer, except in very exceptional cases where the præ-patellar aponeurosis remains intact and unless contraindicated by age and constitutional conditions. As to operation, that by arthrotomy and suture, either of bone or overlying tissue, should be adopted. Here the surgeon can determine the exact condition of the parts, evacuate the blood from the joint and absolutely satisfy himself as to the accurate coaptation of the fragments. Disastrous results have followed this operation, but they can all be traced to one cause, viz, sepsis. Pilchner,[26] in 1890, collected 132 cases operated on by the following surgeons: Phelps, 44 cases; Dennis, 30; Fluhrer, 16; Stephen Smith, 15; Lucas Championniere, 14, and MacEwan, 13. To these can be added 5 cases by Pilcher and 11 by R. Park,[24] in all 148 consecutive cases without any bad result. The same writer in summing up the situation at that time writes: "It is apparent, as we view this whole question dispassionately, that the justifiability of arthrotomy and suture of the patella after fracture, depends entirely upon the reliability and adequateness of the resources which surgeons possess to prevent septic infection of the wounds made. Now this cannot be a matter of theory; it is a matter of experience and practice; 148 cases in the hands of different surgeons, in which the knee joint is widely opened and the constituents of the joint freely handled for considerable periods of time, and all with immunity from septic infection, is sufficient demonstration that reliable and adequate precautions against harmful sepsis are possible to be obtained by sufficient care and knowledge. And, *per contra* the disastrous suppurations, entailing many times amputation and death, that have been reported from other observers, show the results that may follow imperfect antiseptic details and warn against the indiscriminate practice of the operation." This is equally true at the present day. All operative procedures, with the exception of Treves, modified use of Malgaigne's hooks, exclude the possibility of determining the condition of the præ-patellar aponeurosis and cannot guarantee the accurate coaptation of the fragments.

# CLINICAL LECTURES.

## STRABISMUS, OLD DISLOCATION OF SHOULDER WITH INJURY OF BRACHIAL PLEXUS, PROLAPSUS RECTI.*

ROSWELL PARK,† A. M., M. D.

This first case is one strabismus, a condition inwhich one or other rectus muscle is in a state of contraction or is naturally two short, and where the indication is to relieve the inequality by dividing the short tendon. You have seen tenotomies done scores of times for the relief of club foot and similar conditions. In such cases the operation is done subcutaneously and with aseptic precautions. Here, although the instruments used are aseptic, we cannot be sure of excluding bacteria from the wound and it is left open.

Most cases of cross-eye are due to hypermetropia. For distant vision the axes of the eyes are parallel, for near objects, they converge. The strain of focussing the eyes on near objects causes a spasm of the internal muscles and indirectly an actual shortening of one tendon or both.

After doing away with sensibility by means of a four per cent. solution of cocaine, the eye speculum is put in position. The little operation leaves a small raw surface, it is well therefore to use a boric acid collyrium for a few days, but these wounds about the eye seldom go wrong. The patient instinctively keeps the eyes clean during the process of healing and the tears are saline and to some extent antiseptic. If, therefore, the instruments are clean at the begining septic infection is unusual, and although the wound is an open one, it practically heals by first intention. For forty-eight hours after operation, cold applications are used to prevent too large an ecchymosis and outpouring of blood. After this the eyes are used moderately, for too long a rest would weaken the muscles. Even after twenty-four hours, the eyes might be used for a time and then rested while cold applications are used.

---

The next case is that of a man between fifty and sixty years of age. Five months ago he fell from a high straw stack and injured his shoulder. His arm was paralyzed, or at least useless, immediately after the accident. Some hours later a number of local physicians saw him, administered an anæsthetic and made some manipulation of the shoulder. From this meagre history, it is impossible to decide as to the exact nature of the injury and whether he is right or wrong in blaming his physician for the present uselessness of the arm. The shoulder is at present almost completely ankylosed. I can move the arm, but the scapula moves with it. The deltoid is atrophied and there is paralysis of most of the other muscles of the limb. He cannot move the fingers nor can he feel anything in the hand. The head of the bone is displaced downwards in subcoracoid dislocation. It is altogether probable that at the time of the accident, the head of the humerus was driven with crushing force against the circumflex nerve so that the symptoms of deltoid paralysis are the inevitable result of the injury. It is not quite so easy to dispose of the responsibility for the dislocation. It is evident from the account of manipulations under anæsthesia that a dislocation was diagnosed or at least suspected. It is possible that the capsule was so extensively lacerated that reduction of the dislocation was readily accomplished but that the head of the humerus slipped out of place again later, perhaps on account of carelessness of the patient.

The shoulder is at present utterly useless, it is tender and painful and there is complete loss of function. There remains only one indication for relief, namely to resect the head of the humerus and allow a new joint to form. It may be that the paralysis is perpetuated by the pressure of the bone on the brachial plexus. The patient is not too old to make a good recovery from the operation and there is practically no contra-indication. The only question is whether the nerves will recover their proper function after the removal of the head of the humerus. I have made no promises to the patient on this score. After the operation has been recovered from, we

† Prof. of Surgery University of Buffalo.

must begin with massage and the continued current passed through the nerves so as to thrill them with something like the original vital current, whatever that may be. We must also use the faradic current to stimulate and restore nutrition to the muscles. Hypodermic doses of strychnine, which is the best nerve stimulant, will also be used. But any or all of these means would probably be useless without the removal of the bone which now acts as a foreign body. I must remind you that the circumflex nerve which supplies the deltoid is notorious for the frequency with which it is injured in accidents to the shoulder joint. I have repeatedly known patients, lawyers and the laity in general to blame a doctor for this paralysis when he was entirely blameless.

Now that the patient is anæsthetised, I find that there is a little mobility of the shoulder joint which was not obtainable before. This, however, does not alter the indications for operation. The incision is ordinarily made along the bicipital groove, but here there is no object in trying to avoid the deltoid and I shall go through the remnant of that muscle. I have now come to the head of the humerus lying beneath the coracoid process and the chain saw is passed around the surgical neck of the bone. After sawing off the bone, there is little hemorrhage. The wound is closed with four catgut sutures, leaving a little space at each end for drainage. Iodoform is dusted on and the neighboring skin smeared with a sterilized ointment of resorcin and naphthalin. Over this the ordinary antiseptic dressing is applied.

---

The next patient is a decrepit woman of 75 who has had prolapse of the uterus for about 20 years. This, however, is not the condition for which she now seeks relief. A few days ago she fell down a short flight of stairs and hurt herself in some way—she does not know exactly how. Then she experienced pain in the rectum and the bowel protruded causing her great distress. She has had only one small stool in three days. Along with her prolapse of the uterus, I find that she has a complete rupture of the perineum which has undoubtedly predisposed to the prolapse of both viscera.

The most frequent cause of prolapse of the rectum, when there is no hemorrhoid or other anatomical alteration, is long continued constipation. Not only is the lower bowel stretched by the retained fæces but after a time the sphincter loses its tone and in some act of straining, the rectum is pushed out. Prolapse of a pile is quite a common occurence and one which may be mistaken for a prolapse of the bowel proper. In fact, whenever there are aggravated piles there is a tendency to true rectal prolapse in addition. Prolapse of the rectum is quite common in children and especially in little infants. It occurs during the straining of defecation and often goes back of itself or it is recognized by the parents or nurse and returned at once as it always should be. Sometimes it is necessary to give an anæsthetic in order to reposit the bowel. The red cuff of mucous membrane is easily distinguished from the surrounding skin. In old cases in which the bowel has remained outside, the mucous membrane becomes greyish and leathery and partakes of the character of skin.

The best drug for prolapse of the rectum is ergot, not given by the mouth but in suppository. For a little child, a gelatine coated pill of ergotin (ten to twenty centigrams) may be used as a suppository after each defecation. In a case of long standing, however, more radical measures are necessary. There are two ways of operating on such cases. If the bowel goes back easily and simply gives trouble by its tendency to fall out again, you may make ten or twenty linear cauterizations, parallel to the axis of the rectum. Each stripe made by the actual cautery leaves a linear ulcer and as the ulcers heal, there is cicatricial contraction sufficient to restore the rectum to its normal size. The connective tissue of the scars also furnishes an artificial rigidity such as the rectum naturally possesses but is lost in the prolapsed bowel. This case, however, is a different one from what I have described. The rectum has remained outside the body for several days, it can not be returned easily through the anus, in fact, it has become somewhat strangulated. The best way to treat this is to regard it as we would a protruding mass of hemorrhoids, that is as a foreign body to be removed. The cuff is split longitudinally and each half snipped off with scissors in sections, suturing as the excision progresses, so as to control hemorrhage. The operation is a simple one because the mass is entirely outside of the body.

# COMMUNICATIONS.

## GENERAL PARALYSIS OR PARALYTIC DEMENTIA.*

D. R. PELTON, M. D., † Topeka, Kansas.

This disease offers to us a large field for study, for pioneer work, notwithstanding the disease has long been known.

There are, indeed, so many phases of nervous disturbance with mental derangment classified as dementia or general paralysis that it has been and is now a question by some authors if we have not classified several diseases as one.

Then again, the early symptoms are are so obscure that it is difficult to make a diagnosis sufficiently correct to give the patient the benefit of an early and intelligent treatment.

While heredity unquestionably furnishes a basis for its development, there are yet other factors equally as potent in their effect, viz: The rapid push of American trade, the arduous tasks and struggles for promotion in our present system of education as well as in immoral practices and dissipation.

The need of our profession of to-day is an early recognition of these cases which have a paretic tendency. This is not easily done, perhaps, in the field of general practice, for the classification of the various nervous derangements and their phenomena would be as laborious as the naming of the stars in the canopy of heaven. But enough can usually be seen to suspicion some mental or nervous derangement and justify the aid of a consultation, as you would call an oculist or gynecologist, and classify as early as possible the functional from structural diseases, the systemic from the local, and thus fix a basis from which to establish intelligent treatment.

Rather than weary with a long essay on the history of this disease, or with the anatomy, physiology and histology of the brain which you all have access to in medical works, I will simply report three cases out of the number which have come to me, and although the nervous phenomena were well-marked, the true nature of the trouble was not disclosed to their family physician and friends.

Case 1. Mr. A., a contractor, aged 50, while on duty received an injury of the right leg from a fall, and for several weeks was obliged to walk with crutches. Suddenly paresis developed in the right arm. At the expiration of about three weeks (entirely discarding the crutches during the time) he came to me through the kindness of his physican for examination and treatment.

On investigating the case, I found incoordination in walking aside from lameness from fracture, a stiffness and unwieldiness of the muscles of both legs and dizziness. A nearly normal sensibility in the right arm and hand, but motor power greatly diminished. There was also, incontinence of urine, loss of sexual power and constipation from lack of peristalsis, (these latter troubles having come on gradually since a severe sickness about nine years ago) constantly soiling his bed and clothes, to which he seemed to pay little attention.

He had also deafness in the left ear both with and without contact, coming on simultaneously with the vesical trouble; he also complains of or describes formication of the left face, by leading him indirectly with questions.

I found, too, some vaso-motor disturbance, and a stolid mental state, but he was excitable and fault-finding at times, was troubled with insomnia, had hallucinations of sight and sound, saw persons walking around his bed, beautiful flowers on the wall; said they disturbed him, but said, also that he knew they were aberrations; that is, he was able to correct the hallucinations as he did also the illusions which he had.

These statements were not voluntary, but drawn out by conversation.

His speech was a little blurred, psychic word tract sluggish; patient admitted abrasion and sores on glans penis in early life, but they were said not to be of a syphilitic nature. Also admitted making

* Read before the Kansas State Medical Society May 12, 1893.

† Neurologist for A. T. & S.F. R. R. Hospital Association.

liberal use of spiritous liquors, although not to the extent of drunkenness; his history dated back some nine years.

Case 2. Mr. S.; a farmer, aged 31; single; has ataxic speech and unsteadiness of gait and dizziness, which has come on slowly for the past three years; mental condition is sluggish and came on gradually for eight years past, at which time he was disappointed in marriage. His father died aged 50, of pneumonia; he has a brother similarly effected.

On examination I find knee reflexes good, no ankle clonus, sensation normal but slow, muscle sense impared somewhat, incoordinate locomotion, feet stand apart, he inclines toward left side, left shoulder droops. Some difficulty in standing with eyes closed, muscle strength good, uvula deviated to the left and left pillar of fauces droops and its sensory reflex is lost. Tongue protruded with difficulty. The pupil of the right eye larger than the left and less active to light. Memory poor, mind sluggish, despondent and abstracted, attention slow and of short duration. Bulbar trouble. Speech under effort explosive. He was treated for catarrh and afterwards sent to a specialist for nasopharyngeal tumor; none found, but paralysis of palatal muscles; referred to me for examination and treatment. April 9th, ecchymosed palate slough on pharynx and uvula from loss of inervation.

Case 3. Mrs. O., aged 52, wife of a financier. The history of her case gives a gradual change in her disposition which came on after a heavy financial loss, six years ago. Great emotional excitement, fits of crying and despondency, with vasomotor disturbance within the last three years, followed by hypochondriasis and suicidal suggestions. She has delusions of pending starvation and friends turned into enemies, is easily excited at times. is insomnolent. Has decreased in flesh from 200 pounds to 125 pounds. Has weakness in right leg with formication and hyperæsthesia, tactile sense about normal; had decided paresis in same leg ten months ago. Right leg above knee measures one inch less than left, and below knee one and one half inch less. The tongue on protruding deviates to the right. Reflex in left eye normal, but absent in right, pupil reflexes normal; at times quite talkative. Urine on examination diabetic and history seems to indicate its existence for several months.

This case also has some peculiarities; just how much the diabetic urine depends upon the nervous derangement and how much of the nervous derangement depends upon diabetic urine you may conjecture.

I have chosen these cases on account of their opposite characters.

As you will observe, the departure from health in the first case was in the sensory and lumbar cord-center and later affected the mental and voluntary motor powers. While in the second case and also in the third mental deterioration came first and was followed by paresis in its various forms.

There was a time before the decided mental and somatic changes took place in each case that the difficulty rested in the circulation and nutrition simply, but the question arises, what caused these changes in the vaso-motor and trophic centers?

In the one case it might have been excited by alcholic excess or from the sickness in former years.

In case No. 2, a hereditary tendency may have figured, as a brother seems to be following in the footsteps of this disorder, and yet some say heredity is nothing, or if it is, it must be transmitted by a microbe in the spermatic fluid through the germ or through the circulation by the mother.

In both the second and third cases perhaps the exciting cause was the taxation of the emotional centers, thus exciting vaso motor disturbance, resulting later in vacuolization of the spinal and ganglionic and cortical cells, ushering in the somatic phenomena described by some authors.

In cases of paralytic dementia, aside from those of traumatic origin, there are those of a functional nature which sets in action the prenatal tendency. In the primary stage there undoubtedly exists a simple functional and vaso motor disturbance. It may commence in various localities depending upon the excitant cause and having a tendency to assume a progressive course. The capillary vessels in the brain become dilated and leucocytes migrate into the perivascular space, the lymph channels become clogged with accumulation of lymph cells and they press into the inter-spaces. Now changes commence in the protoplasm, for metabolic actions are diminished from less trophic stimulus in the gray matter. The nuclear and cortical cells undergo a granular degeneration of their protoplasmic sub-

stance. The accumulated and enlarged lymph cells surround the cortical brain cells and feed like phagocytes upon the pratoplasm to the evacuolization of their cell body. Perphaps this brain will illustrate the case more fully."

I here present a brain of a man which has some of the characteristic of a paralytic dement. The dura was adherent to the vertex, the *temporo sphenoidal* and *frontal lobes*, and was torn in removing. A degenerative change has taken place from the previous changes of the cortical vessels, causing a porous appearance of the tissue. The vessels are enlarged and torturous. The patient died in a state of delirium and convulsions, succeeding a condition of mental deterioration which had progressed gradually for the past eight years.

Could we expect less in this condition than mental deterioration loss of functional activity and impaired sensibility when the brain and cord are thus affected.

This is but the commencing of a more lasting structural change upon which depends the multitude of paralyses and violent mental conditions that require commitment to state and private institutions for treatment, care and restraint.

Now, the neuroglial cells and leucocytes have undergone structural changes, also, elongating and contracting like connective tissue, multiplying the neuroglial structure and diminishing the myaline, making the condition known as sclerosis of the brain and cord.

To numerate all the changes would take a space I cannot demand. I have only spoken of some of the most prominent changes, that your attention may be called to the investigation of its morbid anatomy.

Now, what can we expect from treatment? Surely in the last stages we have little hope of bettering their condition. In the second stage we may possibly modify or postpone the fatal issue for a time, but in the *early* stage, before vacuolization of the cells has taken place, is when we must meet the demands for interference.

Again, a difficult problem rises before us. How shall we reach the case in its early history when naught but vaso-motor and functional changes can be found. It is only by eternal vigilance we are able to read the hand writing upon the wall, and who in the busy crowd of general practice is able to discern the small dark cloud which in time shall obscure intellectual vision or burst like a cyclone into a fit of maniacal furor compelling some measures of restraint of the unfortunate victim.

While this class of diseases is steadily crowding on in our rapidly developing civilization amid the struggle for supremacy and prosperity with its accompanying emotional tension, our profession is rushing away in search of the microbe or to climb the mount of glory in operative surgery while mental and physical decline is lying at our door unheeded.

To amputate useless members is well, to remove an offending tumor from the abdomen is grand, to excise a growth from the field of the brain with success is noble, but to be able to avert the necessity for the same is the greatest of all.

It is not a matter of new remedies in the treatment of these diseases, for the physician of to-day is loaded down with drugs. As the warrior of old was powerless in his coat of mail (when down could not rise to his feet and when up could hardly stand,) so we are encumbered with a mass of useless stuff which hinders our better use of medicine.

More study of the nature of disease and less attempt at speculative and heroic treatment without an understanding of its pathology would increase our success.

In fact, if our foresight was as good as our hindsight, we might save many a body from being a physical and mental wreck.

But, as hard as we may labor and as high as we may attain in our profession, the generations to come shall climb on and up the towering heights of science until *we* look like mere pygmies below. But we may glory in the fact of being the stepping stone to their success.

**Japan's Jinriksha Runners.**

Jinriksha runners in Japan are hardy fellows. There are not less than 30,000 of them in Tokio alone; and the trade seems a popular one all over the country. One man pulled a jinriksha for over 30 miles, and when asked if he were tired, said: "No, by the grace of God I am never tired," and went on cheerfully for another 10 miles.—*London Million.*

What is becoming in behavior is honorable, and what is honorable is becoming.

# WHY ELECTRICITY SOMETIMES FAILS TO CONTROL UTERINE HEMORRHAGE.*

AUGUSTIN H. GOELET, M. D.†

In a former lecture I told you that one of the principle uses of the constant current was for the control of the uterine hemorrhage, and showed that this was obtained by electrolysis of the tissues in contact with the positive pole. I will reiterate that contact, not instantaneous, but more or less prolonged, is absolutely essential in the majority of instances to produce this result. That is to say, while moderate hemorrhage from the uterus may sometimes be controlled by the application of the ball electrode connected with the positive pole in the vagina, it is more often necessary for a bare metallic or carbon electrode to come into actual contact with the endometrium. The reason for this is obvious when you recall the fact that electrolysis is more pronounced at the location of the poles, i. e., where the electrode is in contact with the electrolyte. The action which brings about this result (the control of hemorrhage), is due to several things operating together; *first*, an electrical osmosis which takes place in the direction of the current from the positive to the negative pole, whereby depletion with paling and drying of the tissues in the vicinity of the positive pole is produced; *second,* the congestion or blood stasis of the uterine body or attached fibroid mass is relieved; *third*, the detachment of adhesions between contiguous peritoneal surfaces, which is one of the first results observed from the use of the current, allows the mass to rise in the pelvis and removes one of the causes of obstructed circulation; *fourth*, cauterization and destruction of the diseased endometrium resulting from the liberation of oxygen, chlorine, acids,etc., at the point of contact of the positive pole with the tissues produces eventually a dense, unyielding eschar which acts as a barrier against subsequent bleeding.

One of the most frequent causes of failure to control uterine hemorrhage with this agent is due to imperfect and insufficient contact of the electrode with the whole endometrium during the application. This may be due to a faulty method of application, or a condition of affairs may exist which will preclude the possibility of placing an electrode in contact with every portion of the endometrium, in which case failure is unavoidable. The platinum sound electrode which is constructed so as to expose any length of metallic surface desired, according to the length of the canal, that the whole canal from the external os to fundus may be exposed to the local action of the current, is necessarily limited in usefulness, because its diameter is so small that contact with the walls of the canal is only possible when the canal is narrow and not dilated. Therefore the attempt to control hemorrhage with this electrode where the cavity is dilated or where its diameter is abnormal will prove a failure. If the canal is tortuous or the calibre is almost obliterated by the projection of an interstitial fibroid into the cavity, or if a sharp angle is formed by the fundus being dragged down by the weight of a fibroid in the upper portion of the uterine wall, it will sometimes be impossible to introduce any kind of electrode the full length of the canal. It often happens that the portion beyond the constriction or obstruction is greatly dilated while that below is of moderate calibre, and if it was possible to introduce an ordinary electrode beyond, effective cauterization would not be possible because of imperfect contact with the walls.

When the cavity is too large to permit the platinum sound being used satisfactorily, the carbon electrodes, which are of different size, are employed and the cauterization is done in sections. A size is selected which will fit the calibre of the canal and it is passed to the fundus, where it is allowed to remain for five minutes while the current is turned on; then, without turning off the current, it is withdrawn a certain distance and another sec-

*A Lecture delivered at the West Side German Clinic in the course of Clinical Instruction in Gynecological Electro-Therapeutics.

†Gynecologist to the West Side German Clinic; President of the American Electro-Therapeutic Association; Fellow of the New York Academy of Medicine and of the New York Obstetrical Society; Member of the Societe Francais d'Electrotherapic, etc., etc.

tion of the endometrium is submitted to the action. This is repeated until the canal of the cervix is reached, which should not be submitted to the caustic action of the current with the large carbon electrode as stenosis would surely follow. When the platinum sound is used, it is not so important to exclude the cervical canal, as the plug of cervical mucus acts as a protection and prevents extensive cauterization here. The introduction of the large carbon electrodes would, of course, remove this secretion. When an accessible constriction, such as narrowing of the cervical canal, prevents the introduction of a carbon electrode of sufficient size to fit a dilated cavity above, I dilate with a steel dilator.

I have been much surprised at the ignorance displayed by some physicians otherwise well informed, regarding the manner of the action of the current upon the surface to which it is applied to control bleeding, and this is another cause of failure, for which, however, the agent is not responsible. It, nevertheless, frequently operates against its more extended application in these conditions, as well as in others where it could be used with benefit if intelligently employed. For instance, a remarkably well informed gynecologist once said to me that he had no confidence in any of the statements concerning the value of electricity in gynecology because it had failed completely to control uterine hemorrhage in a case where he had conscientiously and faithfully tried it. I replied that his failure was probably the result of imperfect contact of the electrode with the endometrium and consequently ineffective cauterization of the whole surface.

"Oh! no," said he, "I am sure that I cauterized the whole surface because I was very particular to move the electrode freely about in the cavity so all parts would be touched by it."

"Did you," said I, "hold the electrode still in one place for five minutes and then move it to another and so until the whole surface had been included, or did you keep the electrode moving about?"

He replied, "I kept it moving all over the surface, of course, so as to be sure no spot was omitted,"

I had some little difficulty in convincing him that an intra-uterine electrode should not be used as a curette, and that it in no way resembled the actual cautery or stick of lunar caustic which takes effect as soon as it touches; but that, on the contrary, the cauterization was due to a chemical action, resulting from decomposition of the tissue elements, which could not occur to any great extent instantaneously, but required prolonged contact. To convince him I had to remind him that a red hot coal could be rolled about in the hand without injury if the motion was rapid. As this conversation took place within the last two years it appeared to me an unwarrantable unfamiliarity with a subject which has been so freely discussed in medical literature. Doubtless, many other failures have occurred in the same way, and many other physicians are deterred from using a valuable therapeutic agent, because errors of a similar nature have caused them to have no confidence in it.

Another casue of failure which in some instances may cause its abandoment, is the attempt to check hemorrhage while the bleeding is very active. This will nearly always fail, (though it is sometimes possible) because the blood flows away so rapidly around the electrode that the chemical action on the tissues is prevented. The action is expended upon the blood filling the cavity, which is constantly refilled as it becomes emptied, and the result of the decomposition is constantly being washed away. The most appropriate time for the application in the case of hemorrhagic fibroids it will be productive of the greatest benefits, is during the interval when there is no bleeding. However, if the applications are persevered with and are properly made they will, in the majority of cases, control an active hemorrhage, but success should not be expected from one or two or several applications at this time. It is here that I think Gautier's Cupric Electrolysis is particularly appropriate. It may be employed in the midst of an active bleeding with certainty, since the decomposition of the copper electrode by the action of the positive pole liberates an astringent salt, the oxy-chloride of copper, which produces coagulation. An additional reason for an immediate result lies in the fact that it is driven into the tissues by electrical osmosis, and the structures for some distance beneath the surface are stained by it. No harm results from the absorption of this salt, as Gautier showed

by experiments upon rabbits. This will be borne out by the observations you have been able to make upon the patients you have seen treated here by this method. You have seen it control hemorrhage when curetting the uterus and packing the vagina with cotton have failed, or when they have only controlled it temporarily. You will recall the patient Mrs K., who was here on the last clinic day. The hemorrhage which had recurred after the use of the curette and washing out of the cavity with a strong solution of iodine, you observed, was promptly and permanently controlled by cupric electrolysis. I suspect malignant disease in this case because the bleeding was so profuse and uncontrollable when the curette was used and because I found that the cervix had been amputated in some other institution about eight months since.

I make no objection to curettment. It has its uses and possesses many advantages. You have seen me make use of it when I thought it more appropriate than the other measures we usually employ here for the control of hemorrhage. The application of the current in these cases possesses this advantage over the curette, however, that it can be employed in office work and an anæsthetic is never required.

These remarks will prepare you for some of the failures you may expect and enable you to turn them into success in some instances. They may likewise enable you to correct some unfavorable criticism regarding the value of this agent.

---

## TRICHINOSIS.

F. W. WILCOX, M. D., Minonk, Ill.

Jan. 9, 1893, I was called to see the wife of A. J., supposed to be suffering from some complication of the mumps. On inquiring into the history of the case, I found she had taken sick about Dec. 19th, with vomiting and diarrhœa, also some pain in her bowels; about the same time her face began to swell and she had headache and high fever, which lasted about one week; after that she was able to be up and do her own work, but still felt bad until Jan. 5th, when she complained of being sore all over and having some headache.

Jan. 9th, when I first saw her I found her temperature 101°; pulse 120, slight cough; no expectoration; breathing short and quick, as if it hurt her to take a long breath; she was lying flat on her back with her limbs extended, arms crossed on her body, jaws set so that she could not open her mouth; said she could not swallow anything but milk and water; felt sore all over, every muscle in her body seemed to hurt her if she moved; pressure on any part of her body or any set of muscles would give her intense pain; face slightly swollen, some œdema of lower extremities; no appetite; bowels constipated, but slept well.

On further questioning, I discovered that on or about Dec. 12, J. had bought some hogs from his brother-in-law, J. R.; these he killed and made sausage of; his wife ate some of the raw sausage at the time, but says that it was only a small amount, and was for the purpose of finding whether it had enough seasoning in it.

I did not make a diagnosis on that visit, but took a portion of the sausage home with me, also a piece from each ham and made a careful microscopical examination of it. I was able to find trichinæ in large numbers in it. I then sent some of the pork to Dr. Melvin, Gov. inspector at Chicago, and he cornfimed my diagnosis.

My attention was then called to one of their children, a boy about two years old, who they said had been sick some time before with diarrhœa and vomiting, then took cold.

On examination I found the boy thin and emaciated, no appetite, a cough, dullness over the lower part of the left lung and with some coarse mucous râles over the other lung. He was cross and whinned most of the time; would cry if touched; his face was somewhat bloated; lower limbs pitted on pressure; had no appetite;

bowels constipated; temperature normal; pulse 110; slept poorly.

J. said that before his wife took sick he had a sick spell, which lasted about one week; he was taken with vomiting and diarrhœa and he felt like he had rheumatism all over; had no cough and a good appetite after he got over the first sick spell.

At my first visit I noticed his face was bloated and that he talked hoarse; he said he felt tired and had some headache, but was able to be around and look after his stock and do some light work. He was a hard drinker and was more or less under the influence of liquor all of the time.

He at first claimed that it was not trichina and would not give any information concerning himself.

Two days later I made my next visit and found the woman much better, with less pain, could open her mouth about one half inch, could move her arms slightly, but had not slept well the night before; had taken milk freely but could not swallow solid food; cough about the same; temperature 101°; pulse 110; bowels had moved from the effects of a dose of senna-tea; she still lay on her back and could not move without its hurting her. The boy was about the same in all respects.

J. said there was a man at the next house who wanted to see me; before going to see him I made inquiry and found that J. had given him some of the sausage. When I called to see him he said he had eaten some of the sausage but it had been cooked in a skillet; but the people with whom he lived said he had eaten some of it raw. He had no vomiting or diarrhœa at any time, only a slight headache and thought it only a cold. His face and whole body was slightly swollen; could not sleep well nights; sweat most of the time, and large drops of perspiration formed on his forehead and nose while I was there. He felt better in the morning and worse at night; said he could not breathe well at night and his feet swelled more then; had a bad cough which sounded hoarse and brassy; no pain in the lungs but some mucous râles over both of them; sore in all muscles, painful to move and would sit in a chair by the fire all the time complaining he would be too cold if he moved away from it; his temperature was normal; pulse 90; bowels constipated; appetite poor.

My next visit was Jan. 15th. The woman had not slept well since I last saw her; sweat all of the time; had pains in her breasts; coughed continuously; had a profuse white expectoration; had difficulty in breathing and felt all the time as if she would choke, and her throat pained her very much. I was unable to make a thorough examination of her throat as her mouth could be forced open but a little; her throat looked red but not swollen.

The soreness in the muscles seemed better, except in the right leg, which pained her more than it had at any time; could use her hands better, but at times would have cramps in her fingers which lasted only a short time; pressure over the joints hurt her as much as pressure on the muscles. The tongue was slightly coated; temperature 103°; pulse 150; respiration 35; bowels had not moved from the oil given the day before; she lay on her back; appetite poor.

The next day she seemed about the same excepting the choking sensation in the throat which made her breath hard, somewhat like a child with the croup; she coughed continuously and frequently expectorated large quantities of mucus.

About eight o'clock she went to sleep and slept two hours, then awoke with a hard fit of coughing and had much difficulty in breathing, but felt easier after a time; then called all her friends around her and said she was going to die; soon she fell into a restless sleep and awoke in about an hour; had a hard fit of coughing and then died. She was not delirious any of the time she was sick.

Jan. 19th. The boy's temperature was 100°; pulse 110; had slept but still had sweats; would sit on the floor and once in a while would play with the other children; drank milk freely and ate some potato; cough was less and dullness over his lung was not so marked; slight pressure on muscles would not produce pain; lower limbs still swollen; diarrhœa lasted but one day.

The neighbor, J. A., was not so sore in his muscles; had been able to walk to the front of the house, but said it made him very tired. His cough was about the same as at my last visit; had mucous râles over the lungs; his bowels moved every other day; appetite was somewhat better; rested well all night; his clothing was wet with perspiration when he awoke in the

morning; temperature normal; pulse 90; limbs still pitted on pressure.

Jan. 22d. I was called to see K. E., a sister of J's. wife; she claimed all the time her sister was not suffering from trichinosis, and to prove it to her friends ate a piece of raw sausage in their presence the day before her sister died. At the time of my first visit she complained of a headache, vomiting and diarrhœa; temperature 102½°; pulse 120; face swollen, especially around the eyes; had no cough; no œdema of extremities; no pain in the muscles, but a poor appetite.

Jan. 24th. The girl, K., has slept well since my last visit; temperature 100°; pulse 90; had no headache; face still swollen, but not so much as before; perspired about the mouth and nose; lower limbs pitted on very slight pressure; her bowels had moved about three times that day.

Her brother E. had eaten some of the sausage on the 14th, but had been well until the 26th, when he was suddenly taken sick while at work with diarrhœa and became so weak he could not continue his work; he did not vomit at any time but felt an inclination to do so all the time. When I next saw him he still had the diarrhœa and his face was still swollen and puffed about the eyes; his brother said his face had been swollen for several days; temperature 99½°; pulse 100; no appetite; no cough; no pain in limbs and slept well at night.

Jan. 31st. E. felt much worse; face, neck and arms swollen; hands would pit on pressure; hurt his neck to move his head; temperature 103°; pulse 110; tongue coated; back and headache; complained of being cold all of the time, although he had on a heavy coat all the time and was sitting near the fire; his bowels had not moved for 24 hours although he had taken a tablespoon full of Epsom salts the night before; had not vomited but felt like it all of the time; made more urine than usual but of a very high red color; in fact all of them were troubled in the same way except the child who made very little for about a week.

The child's temperature was normal; pulse 90; eats well; sleeps as if in good health; no œdema, but still has pain from pressure on the limbs; his bowels move once a day.

K's temperature 99½°; pulse 90; eats and sleeps well; perspires some about the face and is somewhat troubled with night sweats; says she feels much better and was able to be moved to a neighbor's house.

Feb. 4th. K. feeling much better; temperature 99°; pulse 85; appetite good; sleeps well; some œdema of the face and limbs; able to do some light work but perspires freely at night.

E's temperature 101°; pulse 100; appetite better; and sleeps more; still complains of being cold and wears an overcoat about the house; bowels costive; face still swollen but not as much as it had been; a slight hacking cough and night sweats. Little boy's temperature normal; eats more and sleeps better; no cough; some diarrhœa; at times œdema of the limbs; looks thin and pale.

A's temperature normal; appetite and sleep improved; no cough; slight œdema of the extremities; night sweats but none during the day.

Feb. 10th. K's temperature 99°; pulse 85; eats and sleeps well; bowels costive; no cough; limbs pitted on pressure; is able to do house work; no soreness of the muscles but tires very easily.

E's temperature 99½°; pulse 90; sleeps very well, perspires most of the time; slight cough; feels a little stiff in the muscles and short of breath if exercises, but is able to be out of doors on pleasant days; bowels costive.

Little boy still improving, with occasional diarrhœa.

J. A's temperature normal; eats and sleeps well; no cough; no soreness of muscles; no sweats, except when exercising, and is able to go to town five miles distance.

February 16th. All came to my office, a distance of nine miles. Temperature normal. To all appearances they all looked well except E. and K., whose face pitted on pressure; appetite good; did slight work out of doors most of the day.

From that time they came to the office every five days. The œdema decreased and appetite and strength improved so that by March 1st. the men were all able to do hard farm work and to all appearances were well.

The treatment I used was 5 gr. of calomel every morning and a tablespoonful of Epsom salts at night for three days, which kept the bowels moving about three

times a day. After that I gave Hall sol. of strychnine and pepsin, so they would get $\frac{1}{20}$ gr. of strychnine with 10 gr. pepsin. If they coughed any I gave them a mixture of carb. ammonia and paregoric. For the first two weeks all took liberal doses of whiskey and wine, after that drank it about three times a day. At first the diet consisted of milk and eggs, and as they improved they were allowed to eat whatever they liked.

The hogs were of the Poland China breed; were raised on a farm in a large pasture; they were fed on corn; no house slop ever being used; in the pasture was a corn crib and a cow shed which at one time was infested with rats. The two that were killed were picked out as the fattest and best meat hogs on the place; they were about 18 months old.

# SOCIETY REPORTS.

## THE CLINICAL SOCIETY OF LOUISVILLE.

*Stated Meeting, May 2nd, 1893.*

The President, Dr. I. N. Bloom, in the Chair.

### MENINGOCELE—OPERATION.

Dr. W. O. Roberts: I have here a child six months old whom I saw for the first time last week. I was called to remove what was thought to be a sebaceous tumor of the scalp. Upon examining it closely I was pretty certain it was a meningocele, and the aspirator confirmed the diagnosis—the fluid drawn off was as clear as spring water and measured six drachms. The tumor is located just back of the posterior fontanelle.

This is the third case of meningocele that has come under my observation. The first was a patient of Dr. Cottell's; the meningocele was situated at the union of the two halves of the frontal bone. Union had taken place in the bone and the meningocele was shut off from the interior of the cranium. The tumor has split open, and dissected and the child got well without any trouble.

The next case was a child four weeks old that had a meningocele as large as a hen's egg at the posterior portion of the skull, between the two halves of the occipital bone. When the child cried the tumor became quite tense; I advised its removal. The patient was brought to me by Dr. Milner, from Breckinridge County (Ky.). I made an elliptical incision over it and dissected the tumor out thoroughly, then transfixed its neck with a double thread and removed it. There was an opening between the bones fully one-quarter to one-half inch in width. I expected of course that this operation would be followed by a recurrence of the growth or by hydrocephalus, as is frequently the case, but I am glad to say the child made a good recovery. It has been a little over three years since the operation was performed, and the doctor writes me that the child is as sensible as most children of that age.

### DISCUSSION.

Dr. I. N. Bloom: I would like to ask Dr. Roberts what he expects to do with the case presented to-night.

Dr. W. O. Roberts: I shall aspirate it for a while but if it continues to refill I will remove the sac. I would like to know if any of the gentlemen present have ever operated upon a meningocele.

Dr. I. N. Bloom: I have read of cases being operated upon abroad even where there was a portion of the brain protruding, with very good results.

### MEASLES AND SCARLET FEVER.

Dr. P. Gunterman: There is quite an endemic of measles and scarlet fever in my neighborhood. About twelve weeks ago I was called to see a child nine months old which had been sick two or three days; I found it with distinct scarlet rash and with all the evidences of scarlet fever. I treated it for such and in the course of five or six days it was doing very nicely.

On my visit the next day, I found the child extremely ill, and broken out with rubeola thickly and thoroughly; this went through its regular course and in the course of ten or twelve days the patient seemed to be getting well; about two or three days after that it showed some evidences of fever again and became thoroughly anasarcous, which to my mind indicates that the child had scarlet fever to begin with. I believe this is the first case of scarlet fever I have ever seen followed so directly by measles. Since then I have treated a family, and am treating them now, five children, one of them has had scarlet fever and had measles when a baby, so I am told by the mother. The oldest, a girl about ten years of age was taken ill with vomiting, headache, etc. and the second day broke out with a scarlet rash. She went through the regular course without an untoward symptom and in ten days was quite convalescent. Then the next a girl of eight years was taken ill with vomiting, purging, quite a high fever, and on the second day had quite a distinct scarlet rash. On the fifth day after breaking out with scarlet fever, she developed a distinct case of measles. The other two children, girl five and boy two years of age, had all the symptoms of scarlet fever with distinct rash, followed in four or five days by the eruption of measles. This makes six cases of the kind I have seen, and I wish to know whether it is a common thing. With me it is certainly very unusual. I might also say that the oldest girl who did not develop measles had this disease when a baby.

DISCUSSION.

Dr. J. W. Irwin: I do not know that I have ever seen anything of the kind in my experience. I simply want to make one statement, that I have never had a death from measles in my practice. I have seen a great many cases, some very severe ones, followed by the usual complications, but in every instance recovery has resulted.

Dr. Wm. Bailey: It is not a very common occurrence, and yet it is very evident by these cases that two specific causes may be operating at the same time. Evidently the poisons were introduced very nearly at the same time, as is shown very clearly by the day on which the eruption took place in the cases referred to by Dr. Gunterman. However, the children would have had fever nearly the whole time anyhow from measles, as measles come out the fourth or fifth day. I believe the average is the fourth day for the eruption from measles, and the second day for the rash of scarlet fever. The first case spoken of shows clearly that it was a case of scarlet fever, as we do not have anasarca so frequently following measles as we do scarlet fever. It is true that we have at the beginning of some of the eruptive diseases an eruption that simulates scarlet fever, but the history of this case shows that it was a case of genuine scarlet fever. Then in the second family, Dr. Gunterman reports a case of scarlet fever which was not accompanied by measles, because protected by a previous attack, which I think goes to show that the others were clearly scarlet fever and measles combined and we know that one of these does not protect us against the other. Sometimes one eruptive disease seems to be held in check by the prevalence of another, in which the first runs through its course and somewhat delays the second. The cases are very interesting to me; I did not know that scarlet fever was prevalent to any extent in the city. I have seen a good many cases of measles, particularly in certain localities.

Dr. Irwin has been very fortunate not to have had a death from measles or any of its complications. I saw a great many deaths from catarrhal pneumonia during measles during the war.

Dr. W. O. Roberts: I would like to make continued report of a case. At the last meeting of this society I reported a case upon which I had performed an epicystotomy for the removal of two pieces of catheter from the bladder. The gentleman went home soon afterward, and I now learn that the wound has entirely healed and he is passing urine the natural way.

---

SARCOMA—OPERATION.

Dr. A. M. Vance: Two months ago a lady was brought to me from New Hope, Ky., forty-six years of age, who had a tumor just back of the right ear of twenty years growth. The tumor had never been the source of any trouble until two weeks before she came to Louisville, when she suffered some intermittent pain, with con-

siderable increase in size of growth. Upon examination I took it to be an ordinary sebaceous cyst, having taken on fermentative action, and thought its removal would be very simple. I injected some cocaine and made an incision; as soon as I reached the body of the tumor I recognized my mistake from the immense vascularity of the growth, and the fact that it was semi-solid in nature. I immediately put the patient under chloroform and removed the growth; found that it was sub-periosteal, the skull over an area as large as a silver dollar had melted away, the base of the tumor being composed of loose fragments of bone which seemed to have become adherent to the growth, not resembling skull at all but patches of bone. I cleaned it out as thoroughly as I could, the operation being accompanied by terrific hemorrhage, packed the cavity and left it packed with iodoform gauze; then removed it and allowed the wound to contract together and heal up. At the operation I thought the growth was probably sarcomatous in character, which the microscope has proven it to be. At the end of six weeks she returned, the growth had recurred and was double its former size. I attempted a second removal with better preparations than before, and succeeded in getting away the tumor so far as the external part of it was concerned on a plane with the skull. I found the opening in the skull was considerably larger than at the former operation, and the hemorrhage was very much greater; it was absolutely uncontrollable, and the woman came very near dying from the shock, or from chloroform and shock combined with hemorrhage, while on the table. I packed the wound to stop the hemorrhage, packing removed at the end of forty-eight hours the same as was done at the former operation. I only removed part of the growth because the patient became so completely exsanguinated before completing the operation that it would have been impossible to proceed farther. I removed all that portion of the growth which was extra-cranial, but, as part of it was intra-cranial, I did not think further operation justifiable, especially considering the extreme condition of the patient at the time.

DISCUSSION.

Dr. I. N. Bloom: Had Dr. Vance known the exact condition which he would have encountered when the patient first came to him, I would like to ask if he would have operated?

Dr. A. M. Vance: Yes I think I would; there was really nothing else to do.

Dr. W. O. Roberts: I think this must have been either a fibroma or enchondroma originally which became converted into a sarcoma. I have only seen one case of sarcoma affecting the bone of the skull. That was in a negro man twenty-six years of age. The growth occurred on the side of the skull involving the parietal bone. I removed it and removed a portion of the parietal bone much larger than a silver dollar. In this case (the same as in the one mentioned by Dr. Vance) the hemorrhage was excessive. This patient left the city some time after the operation and I never heard of him again.

---

TUMOR OF MESENTERY.

Dr. Roberts (continued): I would like to report one case: About three months ago a man came to me suffering intense pain in the abdomen; I could detect no growth until about six weeks ago, then I detected a movable growth a little above the umbilicus and to the left of the median line. I suggested to him the advisability of a laparotomy, hoping that the growth was located in the great omentum, and that I would be able to remove it. After several days he consented to the operation; meantime he had been confined to his bed and had wasted considerably. I operated at Norton Infirmary. Made a very free opening, and found the growth as large as a goose egg and situated in the mesentery. I decided not to attempt its removal and closed the abdominal wound. He recovered from the effects of the operation without an untoward symptom and since then has steadily improved in general condition. He was in the office day before yesterday and looked like a new man. He says he suffers no pain whatever in the tumor, and it seems to me the growth is reduced to at least one-half its original size.

DISCUSSION.

Dr. W. H. Wathen: Were there any adhesions, and what was the character of the growth?

Dr. W. O. Roberts: I took it to be a malignant growth, the patient had com-

plained of pain for about eight months. There was no history of syphilis, nor of tubercular disease.

Dr. W. H. Wathen: We cannot say what will be the final result of this case because no one can form an opinion so accurate as to the character of this growth as Dr. Roberts who had an opportunity of examining it; but there is a peculiarity about various conditions in the abdomen, particularly about troubles of the liver, gall duct, and the gall bladder, where operations are performed for troubles that have caused a great deal of suffering, loss of flesh, etc., and where compartively nothing was done except possibly the separation of a few adhesions, but the patient improved very rapidly for a time. I cannot explain the growth Dr. Roberts describes in any other way than to consider it malignant, and while the patient has improved, I am inclined to the opinion that after a while there will probably be a recurrence of the old symptoms, then continued progress of the disease, and the man will die of malignant trouble. The case is one of great interest, and I hope Dr. Roberts will watch the future progress of it and report results at a subsequent meeting.

Dr. A. M. Vance: I would like to ask Dr. Roberts why he did not remove the growth?

Dr. Roberts: There was a large tumor in the mesentery and very vascular, and I was afraid of too much hemorrhage.

---

CHRONIC DIARRHŒA; INSOMNIA; ATTEMPTED RELIEF BY HYPNOTISM; ERYTHEMA NODOSUM.

Dr. J. W. Irwin: The first case to which I wish to call your attention is not unique in any way, but one the general practitioner is often brought in contact with and one that serves to show what a long continued drain on the system may give rise to. About a year ago, I was called to see a lady suffering from chronic diarrhœa; she gave the history of having had the disease for five years previously. Her abdomen was immensely swollen and tympanitic from the presence of gas, and every particle of food that she took passed through the bowels fermented, causing great distress. There was a great deal of rumbling in the bowels and her general health was very feeble. There was no perceptible tenderness anywhere and no tumors and no undue enlargement of any of the internal organs. The character of the discharges was as we always see in these chronic cases, light brown in color, showing the absence of bile. The discharges were examined, but did not respond to the test for bile. This patient, after a great deal of care and perseverance, was relieved from the diarrhœa, but her general health did not improve afterward. She remained in a delicate condition and had loss of appetite amounting to general anorexia for quite a while after the diarrhœa had ceased to trouble her.

I was called again to see this patient about two months ago; she had then been for some time under the care of one of those unique physicians known as a "Hypnotizer." She gave an excuse for not having called on my services sooner as some one had persuaded her that the hypnotizer was just the man for her case. She had been suffering from insomnia, and the physician undertook to put her to sleep by means of hypnotism. Of course I was curious to know the methods he employed, and learned about the following from her husband: The hypnotizer began by saying "Madam you cannot go to sleep and I have given you everything I know of to make you sleep; I know of but one more thing that can be used and that is hypnotism, the doctors are practicing it for various conditions in Germany with most satisfactory results, and I wish in this case to practice it upon you." "You go to bed," she did so and the doctor admonished the husband that he must not come into the room. The hypnotizer placed two chairs near the side of the bed, one at the head, the other near the foot, and he sat down upon one and put his feet upon the other, after first removing his coat and shoes. He then told the patient to watch him and not to take her eyes away until she fell asleep. She said that she watched him and watched him until she was tired and blind, but could not go to sleep. She believed that one very disturbing element was the close proximity of his feet to her face. After persevering in this treatment for an hour the doctor gave it up and informed her husband that he could not hypnotize her.

This same patient was taken about a month ago with pain in the ankles, knees

and hip joints of a rheumatic character, but there was no swelling about the joints. There was at first a little fever, the extremities were unduly hot to the touch and exceedingly sensitive, so much so that a blanket caused a great deal of pain over her limbs. A week or so later, spots appeared on her ankles, legs and thighs; they were four or five inches apart, some of them as large as a half dollar of a reddish purple color in the center, very slightly elevated above the skin, indurated in the center but not around the margin. No fluctuation could be detected and no suppuration seemed to be present in any of these spots. Two of the spots coalesced and by some means this spot became chafed and ulceration followed. Now the spot has become enlarged to about the size of the palm of the hand and it is studded over with granulations which bleed upon slightest pressure and which are exceedingly painful. The spots on the other leg, and some of them on the same leg, are disappearing, but this spot of ulceration does not seem to heal nor does it seem to enlarge; it remains in a sluggish condition. The treatment of this patient has been in the line of tonics and stimulants, but she has not improved in health; pain is still present in the limbs; the spots remain out for five or six days, disappear and then reappear. The disease answers the description of acute erythema nodosum but does not seem to yield to treatment.

---

### FATAL CASE OF TYPHOID FEVER.

The next case I wish to speak of is one in which we are all interested, a case of typhoid fever. Four weeks ago I was called to see a gentleman in this city suffering from a very violent attack of gastric colic, the pain seeming to be confined to his stomach. He was doubled up on a couch trying to vomit but could not eject anything. He had taken some food that day and for a few days before had neither vomited nor purged. I relieved him with hypodermatic injections of morphine. Some fever followed the temperature running up to 103° F., which lasted two or three days; and from that time on it was continuous but did not go above 102° F. for a week. The temperature fell in the morning to 109° F. and in the evening to 101½°F.; a few days later it fell to 97½° F. to 100° F. for ten days. There was no pain anywhere, no headache, no aching in any part of the body, no chilly sensations and nothing to apprehend the approach of trouble. The patient had, on the seventh day after he was taken with this violent attack of colic, the peculiar eruption characteristic of typhoid fever on his breast and upper part of the abdomen; a few spots appeared, lasting four or five days. There was very mild diarrhœa, he had from two to three movements of the bowels daily, although he was fed on milk and peptonoids yet digestion seemed to be very defective. One particular feature of this case attracted my attention, and that is why I report the case. From the very onset of the disease the patient had a dry tongue, so exceedingly dry that he could not articulate until his tongue had been soaked in water and softened. The tongue had become very much swollen. He had not taken any calomel before I saw him and I gave him none afterward. The tongue was swollen and was fully three fourths of an inch in thickness, cracked and furrowed, mouth and throat dry, no secretion in the buccal cavity at all, pulse did not exceed, after the first three days, 85 to the minute. This condition lasted until the twenty-second day of the disease. On the morning of the twenty-second he was slightly delirious, talked a little incoherently; he had been sleeping regularly and sufficiently. On the afternoon of the twenty-second day, at four o'clock, he seemed to be considerably revived, his languid condition of the morning seemed to have passed away. I saw him again at eight o'clock in the evening, and his temperature had gone up to 103° F. I gave this patient stimulants by the stomach from the end of the first week and they seemed to have no more effect upon him than so much water. That is to say, there was no increase in the strength of the heart's action. I gave him 6, 8 or 10 ounces of whiskey daily. At eight o'clock that evening he was quite tympanitic, but up to that time there had been no tympanites, abdomen perfectly flat, very little tenderness under pressure and that only in one spot near the right iliac fossa. On this occasion (at eight o'clock) he was in an unconscious condition. Whiskey was given by the mouth and by the bowel, atropia, nitro glycerine, and digatalis injected hypodermically and no effect from

any of the drugs could be observed. He died at 2 A. M.

This case illustrates to me a class of cases of which I saw several, some years ago, when the disease was prevalent in Evansville, Ind., in which I thought the infection was traceable to a barge of corn that had sunk in the river. Upon that occasion I saw a great many cases of dry tongue, but none so striking and none that seemed to be so persistent as this one. In the case reported, there were no evidences of perforation of the bowel further than the tympanites; had this man had hemorrhages or pain in the bowels I might have thought perforation had taken place. This case is the first one I have ever seen where the free use of stimulants appeared to have no effect upon the heart's action so long before the fatal issue occurred. There are two other cases of the disease in the same house now, one has been sick for five days, the other nine days. Dr. Bailey saw the first patient referred to shortly before death occurred; the question of milk supply was considered and Dr. Bailey suggested that a certain dairyman had been selling milk to people who took the disease, that a great many cases in other families were attributed to this cause, they were taking milk from the same dairyman. The hygenic surroundings in this case were good, and it is very hard to say how infection occurred.

DISCUSSION.

Dr. I. N. Bloom: In regard to the first case reported by Dr. Irwin: From the description given, I should consider the case one of purpura. Purpuric spots vary in size from a small petechia up to almost any size. It looks very much like purpura rheumatica gangrænosa. It is well known that purpura rheumatica or purpura hemorrhagica will often go on to gangrænosa; in fact the sharp distinction between purpura hemorrhagica and milder scorbutus cannot be made. From the history of the case, description of the exanthem, its obstinate tendency etc. would be against erythema nodosum as this disease rarely ulcerates, and is a trouble of comparatively a few days standing. It is peculiar in its lumpiness, lumps varying in size and very decidedly elevated. It is never of the color described by Dr. Irwin; as a rule it varies from a fairly dark red to very light red spots, usually painful. From the general description given I should consider it a case of purpura; certainly the only forms of erythema that would suggest themselves would be erythema multiforma and erythema nodosum, except that the spots would be depressed in the center rather than elevated.

## THE LOUISVILLE MEDICO-CHIRURGICAL SOCIETY.

*Stated Meeting May 26th, 1893.*

The President, Dr. F. C. Simpson, in the Chair.

TRAUMATIC ANEURISM.

Dr. Turner Anderson: This young man about two years ago was handling a bar of iron when a piece was detached and penetrated his thigh. He was seen soon afterward by his physician; was little inconvenienced at the time, but soon noticed that there was a tumor on the inner side at about the middle third of the thigh which has continued to enlarge. It is plainly a case of traumatic aneurism.

DISCUSSION.

Dr. A. M. Cartilage: It is certainly a very pretty illustration of traumatic aneurism. I would like to say that I think the best treatment for this condition is direct dissection, after tying above and below the point. I had occasion, some months ago, to see a very large traumatic aneurism in this locality, perhaps a little lower, developing fourteen years after a shot wound with a 22 caliber bullet. It was an enormous aneurism occuring in the practice of Dr. Chenoweth who operated upon it, making a direct dissection

The patient was a negro woman; she made an uninterrupted recovery and is perfectly well to-day.

DR. W. L. RODMAN: I fully agree with what Dr. Cartledge says. It is evidently a circumscribed traumatic aneurism, and the treatment he suggests is the only treatment to be thought of.

DR. A. M VANCE: I agree perfectly with what the two gentlemen have said.

DR. F. C. WILSON: The diagnosis in this case is a very easy one. The thrill is very distinct, the expansive impulse plainly felt, and the bruit can be very readily heard. There is no question as to the vessel involved (the femoral) and no doubt the treatment suggested by the surgeons is the one to be adoped. Of course, the case naturally falls into the hands of the surgeon after the diagnosis has been made by the attending physician.

DR. E. R. PALMER: The aneurism is splendidly located for collateral circulation, and I think the operation ought not to lay the man up for more than a few days. Collateral circulation would be established without any trouble whatever.

DR. W. L. RODMAN: I would say, in answer to Dr. Palmer's question, that the plan of digital compression was very largely followed at one time with excellent results in many cases. This treatment, however, is more particularly applicable to idiopathic rather than traumatic aneurism. Then you have compression by means of different instruments, Reid's method or compression by Esmarch's bandage for instance, which is probably the best of all. In the traumatic variety I think the open treatment, dissecting out the aneurismal sac, is undoubtedly the best.

---

CHOLECYSTOTOMY—RECOVERY.

DR. A. M. CARTLEDGE: These specimens I removed twelve days ago to-day from a patient thirty-four years of age, female. Six weeks ago the patient, a robust healthy subject, never having suffered from anything, was taken with what was supposed to be a case of ordinary colic. Her physician was summoned and, after an examination, he concluded that it was a case of indigestion and gave her a hypodermic injection of morphia which relieved her. The following day was spent in comparative comfort, the patient going about attending to her household duties. On the following night there was a return of the pain which she referred particularly to the epigastric region; the trouble was supposed to be with the stomach, and some common place remedies, catartics, etc. were administered, but without any special relief. In four or five days, however, her physician noticed a small tumor situated a little to the right of the stomach in the region of the gall bladder, concluded that the trouble was in the gall bladder itself, and was due to obstruction of the cystic duct. There was slight jaundice. The tumor, when first noticed, was very small, and continued to enlarge gradually. She had several attacks of pain and, some two weeks afterward, the pain passed away but the tumor remained enlarging all the time. I saw the patient about this time and agreed with the physician that it was a case of distended gall bladder owing to obstruction of the cystic duct.

Twelve days ago she was subjected to an exploratory incision; the gall bladder was found very tense; there were some slight adhesions of a very friable character to the surrounding structures which we easily separated by the fingers; the gall bladder was opened and contents found to be mucus (not bile) and in the cystic duct were found the specimens I present. There were twenty-three calculi in all, five large and eighteen small ones. They were carefully removed and the gall bladder stitched to the abdominal wall and peritoneum, excluding skin. In the case of cholecystotomy which I reported to this society some months ago, I stitched the gall-bladder, carrying the sutures through the skin, muscular coat, and pareital peritoneum. This case did uninterruptedly well, but at the same time there was some little drawing sensation which I thought could be easily avoided by leaving the skin out of the deep sutures. The subsequent course of the case reported to-night was without an accident; there was no pain, no elevation of temperature and not a drop of pus. The wound has closed with the exception of a very small fistula and the patient is up and went down to dinner to-day, (twelfth day after the operation). What I wanted to call special attention to was the manner of stitching the gall-bladder, not carrying the stitches beneath the skin. I think this method is of great advantage,

because when the stitches are carried through the skin it usually gives rise to stitch abscess and pain.

Drs. Vance, Chenoweth, and Scott assisted in the operation.

DISCUSSION.

Dr. A. M. Vance: I saw the patient referred to in consultation with Drs. Cartledge and Scott, and feel that Dr. Cartledge ought to be congratulated upon the rapid and excellent result obtained. I think the question in these cases in the mind of the surgeon is whether he has removed all the calculi or not. I feel sure that they were all gotten out in this case, though for three or four days there was no discharge of bile. I think this is occasioned by the fact that there is infiltration about the duct or irritation due to a certain amount of injury, done in the effort to remove the stone from the duct, which causes obstruction temporarily. Even if bile does not flow for four or five days it is no evidence that the obstruction has not been relieved.

The case reported is certainly an illustration of the good that may be done by cholecystotomy.

---

## THE INFLUENCE OF CHLOROFORM UPON THE COURSE OF NORMAL LABOR, AS SHOWN BY THE TACHADYNEMOMETER.

Donhoff (*Archiv. fur Gynakologie*,) administered chloroform in various degrees to five cases of normal labor, and noticed its influence upon the expulsive force of the uterus and abdominal muscles, as shown by a carefully constructed physiological apparatus. The conclusions reached are in substance the following:

1. The administration of chloroform, even in diminutive doses, exercises a retarding influence upon the progress of labor. The muscular pressure sinks to one-half of the amount of that present before the administration of the anæsthetic. In eight observations the average figures were 1837.

2. The expulsive force of the uterine contractions steadily diminishes during the exhibition of chloroform.

3. The labor pains, besides being weaker, are also more irregular during slight anæsthesia. During deep anæsthesia the intervals between the pains are longer and all the pains are diminished in strength.

4. The pains increase immediately after discontinuing the anæsthetic. The expulsive force of the contractions after stopping the chloroform, compared with the force just before its administration, is, as expressed in figures, 2–3.

5. The labor pains generally continue diminished in power for some time after discontinuing the chloroform. In one case they had resumed their normal intensity in ten minutes, while in two other cases two hours had expired.

6. If the action of the abdominal muscles is only slight, this action is checked entirely by a superficial anæsthesia, but soon reappears after the stopping of the chloroform.

7. The action of the abdominal muscles continues, but in diminished force, during superficial anæsthesia, if before the exhibition of the chloroform it was vigorous in character.

8. Deep anæsthesia abolishes entirely the action of the voluntary muscles.

9. The intervals between the pains become longer immediately after chloroform is administered, and the labor pains, besides being less intense, decrease in numbers about twenty-five per cent.

These carefully conducted experiments show that chloroform, no matter in what degree it is administered, exercises a retarding influence upon the progress of labor. The expulsive forces are lessened and there is no corresponding diminution of the resistance.—*Abstract.*

---

"Longings" of Pregnant Women.—From a study of over three hundred cases. Giles, of London Obstetrical Society, divides the healthy "longings" of pregnancy into three classes: those due to desire for something to check the sense of nausea, those which express the physiological desire for certain kinds of food, and those due in many cases to an auto-suggestion prompted by popular belief. The frequency of longing decreases as the number of conceptions increases.

# The Medical and Surgical Reporter

ISSUED EVERY SATURDAY

ADDRESS
Care P. O. Box 843, Philadelphia.

HAROLD H. KYNETT, A. M., M. D.,
Editor.

RODERIC C. PENFIELD,
Publisher.

316 - 18 - 20 North Broad Street,
PHILADELPHIA.

TERMS:—Five Dollars a year, strictly in advance, unless otherwise specifically agreed upon. Sent three months on trial for $1.00.

REMITTANCES should be made payable only to the Publisher, and when in sums of Five Dollars or less, should be made by Postal Note, Money Order or Registered Letter.

NOTICE TO CONTRIBUTORS:—We are always glad to receive articles of value to the profession, and when used they will be paid for, or reprints supplied, as the author may elect. Where reprints are desired, writers are requested to make a note of that fact on the first page of the MS. It is well for contributors to enclose stamps for postage, that the articles may be returned if not found available.

SATURDAY, AUGUST 12TH, 1893.

## EDITORIAL.

### TRICHINOSIS AND MEAT INSPECTION.

Elsewhere in this issue appears the clinical history of five cases of trichinosis as recounted by Dr. Wilcox. It is the same old story: The mother eats some raw sausage to see if it is properly seasoned; the family eats the sausage but half cooked; several are taken ill; one dies; the physician diagnoses trichinosis; to prove the doctor wrong a relative, with more confidence than wisdom, eats of the sausage and proves the doctor right. The whole picture is another demonstration of the necessity for careful attention to food and food-stuffs, with the emphasis placed upon animal foods.

All meats should be inspected carefully and conscientiously before being used for food. Moreover meats, and especially pork, must be thoroughly cooked before eating; thorough cooking, meaning the application of heat to such degree and for such length of time, as will insure the destruction of living organisms.

Some foreign countries having learned that trichinosis is spread by means of pork, will not allow that article to be placed upon the market until it has passed satisfactorily a thorough examination by the microscope. Americans were rather surprised when the American hog was excluded from these markets, and, as it was a question affecting the pocket, forthwith instituted a government inspection of pork and intrusted the work to the Bureau of Animal Industry of the Federal Agricultural Department. This bureau to prove the practicability of government inspection has, since about two years, examined all pork exported, and with the astounding discovery that while only about 1 pro 1000 of European hogs are infected by Trichinæ, *two per cent. of American hogs are infested by this parasite.*

The bureau inspect pork for home consumption as well as that for export. Not at all! It has not money sufficient so to do. The department is dependent upon Congress for means to carry on its work, and it would seem that, inasmuch as American citizens only are infested and

no advantages are to be gained politically by inspection of pork for home consumption, our busy legislators cannot see their way clear to divert from other channels any monies for this purpose.

Ex-secretary Rusk was severely criticized for expending public funds for pork inspections, and his successor has announced himself opposed to the entire system of meat inspection. It would be pusillanimous to condemn Secretary Rusk's action in this matter or to raise a great cry that the general public has been taxed to pay for the protection of aliens. Undoubtedly it would be wrong to use for a long series of years public funds for such purpose. Probably ex-Secretary Rusk, and as well Dr. Salmon, Chief of the Bureau, would agree with Secretary Morton that the expense of the meat inspection should be borne by the exporters. But, as foreign governments would not accept certificates of inspection from exporting houses, it was wise and prudent in the Agricultural Department to take up the matter and demonstrate that pork officially inspected would be admitted to foreign markets. This has been done and it is a just and righteous attitude now taken by Secretary Morton, that exporting firms should bear the expense of the inspection.

But why should not pork for home consumption likewise be inspected officially? If to protect the lives of Germans, Austrians, Frenchmen or Italians, their governments found it necessary to close the market to uninspected American pork, why should not Americans be granted the same amount of protection? Why should they not be protected against "measley" pork as well as tuberculous beef. This country seems far behind European nations so far as concerns the inspection and regulation of food products.

Medicine is becoming the science of the prevention of disease rather than the art of curing it, and to further this end medical scientists must join with scientists in other lines, and insist upon the inspection of all food meats at the time of slaughtering for the market. Food inspection, to be effective in this country, must be enforced by the Federal Government and be performed by competent scientific men, unbiased and undeterred by any political considerations whatsoever. That this would be difficult under the existing system is unfortunately illustrated by the present administration, in that the Secretary of Agriculture seems to be out of sympathy with the purposes for which the Department was established. He avows his belief that it is not within the functions of Government to carry on scientific investigations, and that it might be a good idea to close up the Department.

---

**Varicose Ulcers.**

Dr. Reboul (*La Semaine Médicale*), treats various ulcers by cleansing, antisepsis and occulsion of the ulcer. He first applies gauze moistened with Van Swieten's solution, or a solution of the biniodide or cyanide of mercury, and covered with oiled silk. After four or five days of this treatment he finds the surface of the ulcer sufficiently modified and covered with granulations to proceed to the use of dry antiseptics. The ulcer is then filled with powdered salol or iodoform and over this salolized or iodoformized gauze is placed, then oiled silk and a tarlatan bandage, reaching from the ankle to the knee. This dressing is not changed for fifteen to twenty days, when the ulcer is found to have healed over completely. If not a second, or possibly a third dressing may be requisite to complete the treatment. In cases where the infection is so ancient that mercurial solutions are insufficient to clean the ulcer, camphorated salol or camphorated naphthol may be necessary. He fills the cavity with gauze imbibed with these drugs and applies then an occlusive dressing.

THERE are two thousand female physicians in the United States, seventy in London, thirty-five in Paris, five in Edinburgh, two in Dublin, and one in Algiers.

# BACTERIOLOGICAL NOTES.

## Anthrax Bacilli in the Mud at the Bottom of a Well.

A very interesting and no less important communication has appeared (*Ann. de l'Inst. Pasteur*, March 1893), from the pen of Diatroptoff, on the discovery of anthrax bicilli in the bottom of a well. An epizootic of anthrax occured near Odessa on land where numerous flocks of sheep were pastured. The sheep which perished were buried and the live ones removed from the place. The sheds and pens were thoroughly disinfected and the sheep returned. Again certain of them were attacked with anthrax. A new change and further disinfection was followed by a third outbreak. The proprietor then observed that only the sheep which received water from a certain well (which had been abandoned in domestic use on account of the brackish taste of the water) were affected. The well was filled up and the disease ceased to appear. A bacteriological examination of the water in the well revealed the presence of no anthrax bacilli in either culture or inoculations. The author examined soil from the pen but with negative results. He then examined the mud in the bottom of the well where he found the anthrax bacilli. They were obtained in pure culture by inoculating rabbits and mice with the mud. They died in a short time and from their organs pure cultures were obtained.

## The Dangers in Antiseptic Midwifery.

Schräder (*Centralblatt f. Gynäk*, No. 16, 1893) has called attention to the exceptions in the success of antiseptic obstetrical practice and endeavors to explain the cause, why the practice is not universally successful. He holds that the poison of puerperal endometritis is often actually diffused throughout the body by intra-uterine irrigations, thus causing a local and probably a harmless morbid condition to become the agent of deadly infection, the veins and lymphatics acting as the diffusers. The stimulation of the uterine muscular tissue by the injections increases the lymphatic absorption. Although vaginal injections are much safer, he believes that they frequently cause a general infection. The fact that a streptococcus has been found to be normally present in the vaginal secretions after labor by Doderlin is considered of importance. Schräder strongly condemns the use of caustics in puerperal ulcers. The reason for the rapid healing of a lacerated perineum when it is repaired immediately after labor is that the parts are allowed to rest. Glöckner's statistics are not favorable to prophylactic irrigation.

## Diseases Probably Caused by Flies.

Surgeon General Sir Walter Moore (*British Medical Journal* 1893, p. 1154) calls attention to the danger of flies conveying disease germs. In a previous article he has brought out this point with reference to Asiatic cholera, but in this article he includes several other diseases such as Enteric fever, phthisis, anthrax and leprosy. This is especially important in places where no special care is exercised in the disinfection of excreta or of soiled clothing. Flies seize every opportunity to investigate all kinds of filth. They are constantly alighting upon all sores on faces, hands etc. whether healthy or affected with contagious diseases. That flies in the East cause "Peenash," or maggots in the nose both of man and animals, is not doubted. The occurrence of isolated cases of cholera and enteric fever and ophthalmia, he thinks may be explained by the conveyance of the germs of these diseases by flies. He suggests the importance of protection against these insects. [The suggestions are exceedingly good and when we consider the habits of flies and the opportunities which they have of taking up bacteria either in their food or on their feet and bringing them to some human food suitable to their development, there is much to support the "fly theory" and arguments against these troublesome insects.—Ed.]

Aluminum is to be used in the construction of artificial limbs, a use to which it seems to be particularly well-adapted, owing to its great strength and lightness.

# ABSTRACTS.

## PERINEPHRIC ABCESS—ENDING WITH PERINEAL LITHOTOMY.

H. I. JONES, M. D., L. R. C. P. E., Etc.

Perineal lithotomy is about the only operation in the whole range of surgery which is performed, as it were, in the dark.

In August, 1891, Sammy Jones, aged two years, was brought to my office, suffering from a swelling of the left lumbar region. On examination, his outward appearance led me to suppose that I had to deal with a case of hip-joint disease. In due time the swelling in the lumbar region became soft, I made a free incision which gave vent to a copious flow of laudable pus, the cavity was washed out with an antiseptic fluid, and a drainage tube inserted. Pus flowed out of the wound for about two months, when it stopped discharging, at which time the little fellow began complaining of pain in the region of the scrotum, telling his mother that a flea was biting him. At the same time she noticed that a good deal of pus was flowing per urethram accompanied by some stones which she could triturate between her fingers—no doubt phosphatic concretions. By this time all the hip-joint symptoms and gait had disappeared. Analysis of the urine showed renal casts, albumen and pus; no doubt the abscess had found its way into the bladder per left ureter. I believe that fifty per cent of the cases reported as cases of hip disease, and cured without lameness or deformity, never have been cases of hip disease at all, but cases of perityphlitis, perinephritis, periarthritis, and various neuroses of the hip and surroundings, all of which are insignificant as compared with true hip disease, which is chronic and slowly progressive.

The little fellow passed out of my hands owing to the long distance to bring him to my office. The next time I saw the little patient was October 27, 1882, when the mother brought him to my office, stating that he suffered excruciating pain during and after micturition. Suspecting a stone as being the cause of his trouble, under the influence of chloroform administered by my friend Dr. O. V. Thayer, I sounded the bladder and detected a large stone.

December 9th, assisted Dr. O. V. Thayer, I preformed the latral lithotomy and removed two calculi, which I now have the pleasure of exhibiting to you. When I first introduced my finger into the bladder, I felt a large ovoid shaped stone, and attached to it, as a tail to a kite, by a tenacious mucus, was the small stone. With some difficulty, after enlarging the wound, I extracted the foreign material, the bladder was irrigated with antiseptic fluid, but no drainage tube was inserted as I find children do better without one. On the fourth day urine passed per urethram; on the 10th day I noticed that all urine passed per urethram, and on the 14th day wound of operation was perfectly healed. He made a good recovery without any special symptom.

The points of special interest are the lumbar abscess, long duration of the case, and rapid repair of surgical wound. The question is this: Was the abscess due to pyelonephritis; was the nucleus of this stone the cause of the perinephric abscess? Pyelonephritis, nephritis, and renal colic, are preceded by nephritic colic, but owing to the age of the patient we could only get the objective symptoms, the abscess passing pus per urethram, etc. As above stated no doubt the abscess emptied itself per ureter into the bladder. The significance of acute lumbar abscesses depends upon the causation and the locality from which they take their origin. The majority of lumbar abscesses are caused by purulent affection of the kidney, or its pelvis, as for instance, renal calculus or pyelitis, but in a large number of cases no affection of the kidneys, or their adnex, can be recognized. Some injury of one or the other must be assumed as the cause. The presence of pus in the urine indicated pyelitis. Was it due to the nucleus of this stone now exhibited, or was the abscess primary in the tissue surrounding the kidney, and due to some injury?

Before closing, if I may be permitted, I will give a rapid anatomical sketch of the

region in which these abscesses are developed, and the relation of the kidney to neighboring organs. As you are all aware, the kidneys are situated on each side of the vertebral column and surrounded by a large quantity of cellulo-adipose tissue. The fatty capsule of the kidney has relations posteriorly with the pillars of the diaphragm, and with the deep folds of the transverse aponeurosis; it also has relations anteriorly with the ascending or descending colon. The fatty capsule is continuous with layers of cellular tissue, which are continuous with the cellular tissue of all organs of the perinephric region. But the continuity most important to note is that which exists between the perinephric cellular tissue of the iliac fossa. The iliac aponeurosis is usually found only in the two upper thirds of the iliac fossa by loose cellular tissue, which is rarely continuous with fibrous tissue. From the disposition of parts it results that the pus surrounding the kidneys will find its way equally easily into the cellular tissue, which forms the immediate covering of the psoas muscle, or into the sub-peritoneal or sub-aponeurotic cellular tissue. This continuity of the cellular tissue of the perinephric region with that of the iliac fossa is the anatomical explanation of the facility with which perinephric abscesses follow the iliac and crural vessels, open into the triangle of scarpa or at the trochanter minor, following the psoas muscle to its lower insertion. Perinephric adipose tissue is continuous with the cellular tissue of the lumbar region beyond the quadratus lumborum between the margin of the latissinus dorsi and external oblique muscle. This continuity of the cellular tissue shows us the course taken by the pus in cases of perinephric abscess, when it is poured out into the sub-cutaneous cellular tissue of the lumbar region to be localized, as in the case before us. So this relation of the perinephic cellular tissue to the iliac fossa, true pelvis, colon, diaphragm, and psoas muscle, will enable us to understand the peregrination of these abscesses.—*Pacific Med. Journal.*

---

## OVARIAN TUMOR WEIGHING ONE HUNDRED AND ELEVEN POUNDS REMOVED FROM A CHILD OF FIFTEEN, WHOSE WEIGHT WAS SIXTY-EIGHT POUNDS.

W. W. KEEN, M. D.

Miss B., of Benezette, Pa., was first seen by me at Driftwood, Pa., February 26, 1892, at the request of Dr. V. K. Corbett, of Caledonia. She was then fourteen years of age and had never menstruated. About eighteen months before I saw her, her abdomen began to enlarge. Six months afterward Dr. Corbett was consulted for an attack of considerable pain in the left side of the abdomen. He found that she was only voiding eight ounces of urine in the twenty-four hours, but under proper treatment this soon reached a quart in amount, and has remained so ever since. He never discovered any albumin in the urine. In October, 1891, she had been tapped by a gynecologist, who is said to have diagnosticated a solid and probably malignant tumor, connected most likely with the liver, omentum, and ovary, and who deemed its removal not feasible.

I found the abdomen enormously distended with fluid and advised very strongly that a small incision should be made in the abdominal wall, so that I could determine the relations of the growth with accuracy. Her father, however, was not present, and had made it a condition that nothing beyond tapping should be done. I tapped her immediately and removed considerably over three gallons of amber-colored fluid. When this was evacuated I discovered a lobulated tumor on the right side of the abdomen, under the liver and apparently attached to it. It was evidently cystic in part, there being at least two cysts perceptible. Each of these I tapped, obtaining from the opper one a light fluid and from the lower one a much darker fluid. On account of her age no vaginal examination was made. The fluids pointed strongly toward an ovarian cystoma. I again advised an exploratory incisino.

April 29, 1890. The patient was finally brought to the Jefferson College Hospital. She had been tapped twice since February, 1892, the last time in February, 1893, when six and a half gallons were drawn off. She is now enormously swollen. The measurements are as follows: From the ensiform to the umbilicus, 16½ inches; from the ensiform to the pubes, 29½ inches (this measurement in myself reaches from the ensiform to the middle of the calf of my leg); circumference, 49 inches. The veins over the abdomen are very large. Nothing can be made out in the interior in consequence of the enormous abdominal distention. Examination of the urine shows no albumin and a very slight trace of sugar (?)

*Operation.*—April 30, 1893. A small incision was made in the median line above the umbilicus, as the greater mass of the tumor lay there. A large trocar was thrust in and evacuated a very large quantity of characteristic opalescent ovarian fluid. The escape of this fluid revealed through the abdominal wall large masses lying especially under the liver and in the right iliac fossa. After this evacuation I enlarged the incision until it measured eventually about eight inches in length, and found an enormous ovarian cyst, reaching up to the diaphragm and pushing everything out of its way. There were a number of moderate adhesions, chiefly to the belly wall and the omentum. The viscera were fortunately entirely free. The pedicle was only 2½ inches broad. The tumor arose in the right ovary, the left ovary being healthy but small.

The weight of the solid mass removed was twenty-seven pounds, and by actual weighing the fluid removed weighed eighty-four pounds, making a total of one hundred and eleven pounds. The child herself weighed but sixty-eight pounds.

After the removal of the tumor I never saw so curious a looking abdominal cavity. It looked almost like that of an eviscerated cadaver in the dissecting-room. The tumor had so pushed the liver to the right and backward, and the stomach to the left that nearly the whole of the diaphragm was exposed, and flapped up and down with the pulsations of the heart. Down the middle of the cavity the bodies of the vertebra were entirely exposed, and showing the aorta and vena cava to their bifurcations, the intestines being a very minor consideration and pushed to each side in the hollow of the ribs and the lumbar region. When the abdominal wall was sutured the abdomen was excessively scaphoid, the anterior abdominal wall lying directly on the aorta and vertebræ. The puckering of the skin, although moderately marked, was much less than I had expected.

When the operation was completed a glass drainage-tube was inserted, and she was put to bed in very fair condition, in view of the gravity of the operation. The tumor was a multilocular cyst.

May 18, 1893. The child has made an uninterrupted recovery. The drainage tube was removed on the fifth day, when the discharge had become almost nothing, but three days later a slight rise in temperature took place, and the discharge recommenced. A small rubber drainage tube was therefore reinserted for a few days. She sat up at the end of two weeks, and will go home as soon as the slight discharge from the drainage opening ceases.

*Remarks.*—I have not had time to search through the literature of ovariotomy, but so far as my memory serves I have never known a larger tumor removed from a child. It weighed just one and a half times as much as the patient. Her recovery has been most satisfactory in spite of a very poor and capricious appetite. The chief lesson the case teaches is the value of an exploratory incision in every case of doubt. Had this been done, instead of mere tapping, in October, 1891, when the tumor was much smaller, the prognosis would have been much more favorable, and she would have been spared a year and a half of needless suffering. What seemed to be a most formidable operation really proved to be almost a simple one, the adhesions and the pedicle being most favorable for the speedy recovery which has ensued.—*Nashville Jour. Medicine and Surgery.*

---

Brillantine is a preparation for the hair, for which the *Bullet. de Lyon* gives the following three formulas:

1. Castor oil 6, castile soap 2, benzoin 2, alcohol 200 gm., attar of roses or of neroil sufficient,

2. Glycerine 10, alcohol 100, rose water 100 gm.

3. Castor oil 6, glycerine 6, benzoin 2, alcohol 200 gm. perfume.

## THE PRESENT POSITION OF THE SURGERY OF THE PROSTATE.

Dr. J. William White, read a paper on this subject before the American Surgical Association. In regard to the nature of the prostatic enlargement it was held that the prostate gland was a part of the sexual apparatus and not chiefly an accessory organ of micturition, and that the growth or growths which make up the enlargement are analogous to the fibro-myomata so frequently found in the uterus.

The changes in the bladder are due to the mechanical obstruction, the circulatory disturbance produced by pressure on the prostatic veins and to septic infection.

The symptoms of prostatic enlargement were discussed at length. In regard to treatment, purely expectant treatment is proper only where the enlargement has produced no symptoms and catheterization is easy and shows no residual urine. Ergot is the only drug that offers any prospect of usefulness, but it is far from demonstrated that it has any distinct effect. Palliative treatment consisting in the systematic use of steel sounds for dilatation and the employment of the catheter is of great value in a large number of cases.

The following operative methods discussed:

1. Overstretching of the prostatic urethra. This is not likely to be followed by good results in cases where the median lobe and the vesical neck are chiefly involved. In lateral hypertrophy where the urethra is simply narrowed it may be of use.

2. Perineal prostatotomy should be regarded as that of choice in cases in which with marked diminution of the expulsive force, and with cystitis there are evidences of widespread degenerative disease or of distinct renal disease, toxemia and general feebleness.

3. Perineal prostatectomy, where the growth can be reached by the finger and is of small size or pedunculated; perineal prostatotomy can always be converted into a prostatectomy.

4. Suprapubic prostatectomy is the operation to be preferred in those cases in which palliative treatment having failed there are unmistakable indications that the local conditions are worse, the general health remaining unaffected.

In conclusion, the speaker said that some time ago the thought occurred to him that possibly if the analogy between uterine fibro-myomata and prostatic growth was a real one, castration might have the same effect upon the latter that oophorectomy does upon the former. At this time he had not read of the alleged prostatic hypertrophy in eunuchs, geldings, etc. He instituted a serise of experiments on dogs to determine the effect of castration on the size of the prostate. It was found that the average weight of the prostate in dogs was 35.3 grams. The dogs were killed at varying intervals after the operation, the longest period being seventy-two days, and in all there was a marked diminution in the weight from 2.5 grams to 5.5 grams according to the weight of the animal and the period at which it was killed.

The author did not wish to be understood as advocating the measures which these studies would indicate. He simply presented the subject as a line of thought which had occupied his mind at odd times in order to have the criticism of the Association. As regards the employment of castration as a therapeutic measure in prostatic hypertrophy, the final answer must be left with the patient. If the time comes when we can promise equivalent results to those obtained by oophorectomy in uterine fibroids, there will probably be no lack of cases willing to submit to the operation.

### Alopecia Circumscripta.

Dr. L. Duncan Bulkley writes, in the Journal of the American Medical Association, that in the parasitic form he employs:—

℞

| | |
|---|---|
| Hydrarg. bichloride | gr.j |
| Lanolin | ʒj. |
| Terebene | mj. |

Sig.—Apply twice daily.

### Strychnine for Snake Bite.

E. A. Thomas, M. D., Assistant Surgeon, Nagino, India, reports, in the *Indian Medical Record*, five consecutive cases of bites by poisonous snakes, in which prompt recovery ensued upon the administration of staychnine, in full doses, repeated hourly until out of danger, which was usually determined after the third dose.

## PTOMAINE POISONING.

Dr. J. C. Gilbertson, of Luverne, Minn., writes upon this subject in the R. I. *Medical Science Monthly* as follows: Many of the common ailments or diseases that the human race is heir to are now universally conceded to be caused by living organisms. Bacteria or microbes have been wandering about upon the face of this earth for nearly 6,000 years, seeking whom they may devour. So deadly and so appalling has at times been their work that humanity has time and again cried to heaven for deliverance. Yet so successfully have these germs labored in disguise that it is only in the latter part of this ninteenth century that they have at all been discovered. The scientist and microscopist, the chemist and bacteriologist of the last ten or twenty years have somewhat succeeded in piercing the curtain and viewing a few of the hitherto unknown actors.

Bacteria are the lowest forms of vegetable life. They are minute, unicellular in structure, and multiply by division and the formation of spores. They split up complex substances into simple elements through the process of putrefaction. Most bacteria are harmless, but some after gaining admission to the body are capable of producing disease and are known as pathogenic.

Recognizing the fact that germs do bear a causal relation to some disease, the question arises, how do these organisms produce disease? Several theories have been advanced:

1. The germs deprive the blood of oxygen.

2. The bacilli accumulate and form mechanical obstructions in the vital organs.

3. The bacilli consume the proteids of the body.

All of these theories have been shown to be defective and none are at the present satisfactory. Hence a fourth and generally accepted theory:

4. Bacteria during their growth elaborate a chemical poison, which is soluble, and which when introduced into the circulation produces fever and the characteristic symptoms. This chemical poison is known as a ptomaine. We will then define a ptomaine as a product of bacterial decomposition. Vaughan gives an explanatory definition and defines a ptomaine as "a chemical compound which is basic in character and which is formed by the action of bacteria on organic matter."

A large number of the ptomaines are inert, others highly poisonous. We will consider the latter only.

This bacterial decomposition may take place in or outside the body. We will therefore, consider ptomaine poisoning in relation to the body from external and internal causes.

1. External causes. Whenever bacteria have under favorable conditions attacked matter outside of the body, and by decomposition have elaborated their characteristic poison, and this again has gained admission to the body, generally through the alimentary tract in food or drink. Under this head is poisoning from ham, sausage, oysters, mussles, milk cream, cheese, etc. We will not discuss each in detail. The ptomaine gaining admission is already in a soluble state, is quickly absorbed, and symptoms usually develop early. There is much similarity in symptoms and they may be grouped under the following divisions:

1. A true gastro-intestinal irritation, in which we have vomiting, purging, cold, clamy skin, anxious countenance and much depression.

2. Purely nervous, sensation of heat, itching, nettle-rash eruptions, swelling, asthmatic breathing, etc.

3. A kind of intoxication, in which we find dizziness, muscular weakness, muscular spasm, paralysis, coma and death.

Treatment—Preventive and symptomatic.

2. Internal causes.

Most of the infectious diseases, suppuration, purperal fever, etc., are conceded and many proven to be due to pathogenic bacteria. We will consider a few:

Diphtheria.—Says Vaughan: "That the Loffler bacillus is the cause of diphtheria no one can now deny. The fact that this germ, although found only at the seat of innoculation causes marked systematic disturbances, indicates that its action must be due to its soluble products."

The bacillus gaining admission to the body and finding lodgment in its favorite location about the tonsils, in the pharynx, larynx or nares, acts as a local irritant producing an exudative inflammation. In so doing it first induces death of the cells with which it comes into contact, particularly the superficial epithelium and the leucocytes. The further action of this necrosed tissue and of the bacilli results in the elaboration of a ptomaine which is soluble, becomes absorbed into the circulation and produces the marked systemic infection. From this point of view we consider diphtheria as primarily a local disease, and the constitutional disturbances as due to poisoning by the ptomaine of the diphtheritic bacillus.

Typhoid fever. Most of the bacteriologists and the profession at large believe that the bacillus of Eberth is the specific cause of typhoid fever. To this belief Vaughan and a few others take exception. At present, however, I am willing to recognize Eberth's bacillus as a cause of typhoid fever. This bacillus, if it succeeds in passing the stomach without being destroyed by the gastric juice, seems to have a special affinity for Peyer's patches of the small intestines. Here it acts as a local irritant, causing hyperemia, death of cells and necrosis, and in so doing elaborates its characteristic poison, by some termed the "typhotoxine," which is largely responsible for the marked constitutional symptoms.

Tetanus.—The bacillus of tetanus is primarily a native of the soil, but is frequently found on rusty nails, fork tines, splinters, etc. The bacillæ, I believe, have never been found in the blood or tissues beyond the point of introduction. Their action is entirely local. Here they multiply and eloborate their ptomaines, which have a special action on the spinal cord and spinal centers.

To bring to a close, I am inclined to the following deductions:

1. Pathogenic bacteria cause disease by the elaboration of ptomaines.

2. The primary action of pathogenic bacteria is local and the constitutional disturbance is brought about by the absorption and action of ptomaines.

How, then, are we to meet and counteract these conditions? Bacteria, being living organisms, are made inert or destroyed by antiseptics and germicides. Ptomaines, being chemical productions, remain uninfluenced thereby.

Our first effort then becomes to destroy the bacilli, and as far as possible to prevent the elaboration of ptomaines. This is best accomplished by early, thorough and continuous local antiseptic treatment.

Our second effort is to counteract the depression and marked constitutional disturbance caused by the absorption of the chemical productions. This is best accomplished by supportives, stimulants and remedies to counteract the prominent symptoms as they arise.

---

### Pruritus.

Dr. Colombini praises the following formulæ:

℞ Menthol..... 10 parts.
Ol. amygd. dulc.....100 parts.—M.

℞ Zinc. Oxid.,
Amyli pulv..... āā 50 parts.
Menthol..... 1 to 6 parts.
Paraffin. mollis.....100 parts.
M. Sig.—Pasta.

℞ Zinc. oxid.,
Bismuth subnitr.....āā 10 parts.
Menthol..... 1 to 3 parts.
Amyli pulv..... 30 parts.—M.

—*British Journ. Dermatology.*

---

### Burns.

The following useful combinations are given by Saalfeld:

℞ Tannic acid..... ʒss.
Sp. vini rect..... f ʒi¼.
Collodion..... f ʒv.
Tr. benzoin..... f ʒss.
M. Paint upon the surface.

℞ Alum ..... ʒj.
Yelk of egg (boiled)..... no. j.
Glycerin ..... f ʒss.
M.

Or—

℞ Alum
Borax ..... āā ʒss
Rose-water..... f ʒv.
Tr. benzoin..... f ʒi¼
M. Sig.—Apply upon compresses.

---

Iron rust on muslin or white goods may be removed by saturating the spots with lemon juice and salt, and exposing to the sun. Repeat if necessary. To prevent the appearance of the spots, when the clothes are being washed, it is well to have them enclosed in a muslin bag during boiling.

---

Ointment for Freckles, etc.; 5 parts of ammoniated mercury, and bismuth subnitrate, 2 parts olive oil, and 8 parts of glycerite of starch; or, 10 to 20 parts of betanapthol, 25 parts each of starch, and zinc oxide, and enough vaseline to make 100 parts.

# THE LIBRARY TABLE.

## BOOK REVIEWS.

*An Introduction to the Study of Diseases of the Skin.* By P. H. Pye-Smith, M. D., F. R. S., F. R. C. P., Physician to the Department of Cutaneous Diseases in Guy's Hospital, London. In one 12mo. volume of 407 pages with 28 illustrations, 18 of which are colored. Cloth $2. Philadelphia, Lea Brothers & Co., 1893.

This Handbook is a reprint, with some variations and additions, of the chapters dealing with diseases of the skin which appears in Fagge's *Practice of Medicine.*

That this monograph should appear in such a notable work, is sufficient to commend it to all practitioners. To the dermatologist, student and teacher this work will be of the greatest assistance, introducing, as it does, the subject in a manner unknown to most modern textbooks. Diseases of the skin should be arranged (as they should be named) like diseases of other organs: *i. e.*, for convenience, either alphabetically or otherwise. The present volume opens with the most common inflammatory diseases, the superficial forms of dermatitis, eczema and its allies, psoriasis, erythema and their allied diseases. Then follow affections of the hair-sacs and cutaneous glands, including ringworm. Next come the deep inflammations and the hypertrophic conditions which result therefrom. Closely allied to the deep chronic forms of dermatitis are the important and well-defined diseases known as lupus and leprosy, and the chapters which treat of these are naturally followed by one on tumors and new growths. Then comes a short section on abnormalities of the cutaneous pigments and of cutaneous innervation, and the subject concludes with a chapter on the practical diagnosis of diseases of the skin in general.

An instructive and useful feature is the introduction of tinted diagrams illustrative of the favorite seats and distribution of cutaneous diseases. This is a point of the greatest practical importance, and one that has been to a large extent neglected by dermatologists since the time of the writings of the late Tilbury Fox.

The volume closes with a section of formulæ, which will prove suggestive and of the greatest assistance to the general practitioner in dealing with this class of troublesome diseases.

---

*Various Forms of Hysterical or Functional Paralysis.* By H Charleton Bastian, M. A., M. D., F. R. S. Philadelphia. J. B. Lippincott Company, 1893

The nucleus of this book was published last year in the *Lancet* in the form of four lectures. The records of several new cases have now been incorporated, and the discussion of the subject has, in reference to some points, been still further developed. Attention is called to the error in employing synonymously the terms "hysterical" and "functional" since there are many examples of functional paralysis which cannot properly be classed as hysterical. Indeed, not more than one-third of all functional cases belong to the hysterical group.

A primary division is made in functional paralysis of cerebral type and of spinal type.

The following table gives the characteristics of the type which are differentiated by the author:

CASES OF FUNCTIONAL PARALYSIS OF CEREBRAL ORIGIN.

| VARIETIES. | CHARACTERISTICS. |
|---|---|
| 1. Affection of kinæsthetic centres in Rolandic and marginal areas alone. | Loss of muscular sense, with motor paralysis. Also slight loss of tactile sense, with defective power of localizing. |
| 2. Ditto, *plus* an affection of sensory region of internal capsule. | Ditto, *plus* more or less complete hemi-anæsthesia. (The paralysis flaccid or spastic). |
| 3. Affection of sensory region of internal capsule alone. | No motor paralysis. More or less complete hemi-anæsthesia (superficial, or superficial and deep, the latter including loss of muscular sense). |
| 4. Affection of efferent fibres from kinæsthetic centres in Rolandic area. | Aphemia or hysterical mutism. If purely motor paralysis of limbs, then no loss of muscular sense. |

CASES OF FUNCTIONAL PARALYSIS OF SPINAL ORIGIN.

| | |
|---|---|
| 5. Affection of pyramidal system of fibres in spinal cord. | Spastic paralysis, with no distinct loss of muscular sense. Also no "cerebral hemi-anæsthesia" or other cerebral symptoms. |
| 6. Affection of anterior cornua in certain segments of spinal cord. | Flaccid motor paralysis, with or without some loss of sensation. No distinct hemi-anæsthesia, and no marked loss of muscular sense. |

In order to form a final judgment in doubtful cases, we are ultimately compelled to rely on the following two sets of considerations:

"1. As functional defects tend specially to affect particular regions of the brain and spinal cord, we have to consider whether the grouping of symptoms met with in the case before us in such as our clinical knowledge has taught us may be due to a defect in one or other of such regions.

"2. We have to consider whether the mode of onset, coupled with the patient's general state, together with his or her immediate and remote history and family history, taken as a whole, most strongly favors the notion that we have to do with a malady due to mere functional defect, or to the existence of some organic lesion.

"This may seem a complicated procedure, and not too calculated to land us in certainties; but unfortunately it is the only safe method available for making a trustworthy diagnosis."

The work is concluded by three lengthy appendices: 1st, The "muscular sense:" its nature and cortical localization; 2d, on the neutral processes underlying attention and volition; 3d, Is there a double representation of touch and common sensibility in the cerebral hemispheres? The book is worthy of a careful reading by those interested in this line of work.

---

*International Clinics.* A quarterly of Clinical Lectures on Medicine, Neurology, Pediatrics, Surgery, Genito-Urinary Surgery, Gynecology, Ophthalmology, Laryngology, Otology, and Dermatology. By Professors and Lecturers in the leading Medical Colleges of the United States, Great Britain, and Canada. Edited by John M. Keating, M.D., LL.D., Colorado Springs, Col.; Judson Daland, M.D., Philadelphia; J. Mitchell Bruce, M.D., F.R.C.P., London, England; David W. Finlay, M.D., F.R.C.P., Aberdeen, Scotland. Volume I., Third Series, 1893. Philadelphia: J. B. Lippincott Company, 1893.

This issue contains fifty-one articles written by fifty prominent men, most of whom are teachers in schools and hospitals of this country and of Europe.

The subjects selected are timely and will be found valuable by the general practitioner; they are not the mere recital of unusual and curious cases, but are those which the average man is likely to come in contact with, and the offering of many new remedies together with the results and effects will be found of great assistance.

The articles, coming as they do from men with large and varied experiences, not only in hospital work, but in private practice as well, cannot do otherwise than impress and instruct the reader.

---

# CURRENT LITERATURE REVIEWED.

---

THE SAINT LOUIS MEDICAL AND SURGICAL JOURNAL

for July. Dr. A. H. Ohmann-Dumesnil contributes an article on

**Erythema Exfoliativum Recurrens,**

discussing several cases reported by other observers and adding the report of a case of his own. The paper is illustrated by cuts showing the patient during the process of skin shedding in one case and the gloves cast off from the hands in another. The treatment adopted by the author, in the case observed by him, consisted in the use of quinine in three grain doses every three hours, as the symptoms of the case were always strikingly malarial.

For the condition of the skin which succeeded desquamation, the following ointment was ordered with complete success, as it proved efficient in relieving the sensitiveness of the denuded integument and caused a disappearance of the pruritus, besides acting as an efficient protective during the complete restoration of the horny layer.

℞ Campho-phenique..... ʒj.
Albolene (solid)..... ʒiij.
M. Ft. Ungt.

A few points which have been noticed by the patient and to which she has drawn attention, are the following: Each attack of desquamation comes on just one week before the menstrual flow. Her attention was called to this circumstance by the fact that it occurred each time in that way, and it can hardly be looked upon as a coincidence. She further states that after taking an ordinary dose of quinine, she experiences a prickling, tingling pain in the thumb. On this account she is inclined to believe that the general desquamation is due to the remedy, but this is evidently a *non-sequitur*.

The author is of the opinion that relapsing desquamative erythema is beyond all doubt a trouble due to disturbance of the trophic nerves.

The treatment is a very simple one, consisting merely in protecting and soothing measures. Whilst in many cases symptomatic treatment has been employed, there is no evidence that it exercised any particular beneficial action, as far as the cutaneous symptoms were concerned. The protective measures employed have certainly had a direct effect as prophylactics in preventing a possibly graver condition which might be induced by irritation due to an extraneous source. Of course, such measures are not only proper and rational, but even imperative. To neglect their application would certainly argue a disregard for the patient, but also a serious disregard for the exigencies of the case in hand.

Dr. C. Bernard Wolff contributes a translation of a paper by Dr. P. G. Unna, of Hamburg, on "Inflammation and Chemostasis."

Dr. W. P. Manton discusses the subject of "The Diagnosis of Abdominal Tumors," showing the various means by which the position, size and probable character of the condition is discovered. The author regrets that abdominal surgery is regarded in some quarters as so simple a branch of surgery that men rush into it without the proper training.

Dr. Frank Woodbury contributes a clinical lecture on the "Treatment of the Gouty

State." In the treatment he regards the use of some good natural lithia water as very essential, the good effects of which he ascribes to the peculiar combination of the various salts which it contains as much as to the amount of lithia present. He thinks the profession is inclined to take too narrow a view of gout at the present day and, instead of the gout being caused by the uric acid in the system, he regards the disease as being responsible for the excess of uric acid.

The remaining papers in this issue are: "Prognostic Aphorisms" translated from the French of Dr. Gabriel Reignier by Dr. Charles Everett Warren; and the report by Dr. C. H. Powell of a "Case of Hæmato-Salpinx and Pelvic Hæmatocele." The patient recovered from the laparotomy.

---

THE AMERICAN JOURNAL OF THE MEDICAL SCIENCES,

for August. Dr. James J. Putnam contributes a paper on

**Cases of Myxœdema and Acromegalia Treated with Benefit by Sheep's Thyroids.**

The author states that the method of administration by the stomach has not failed in any genuine case and moderate quantities are sometimes so effective that we have no reason to conclude that any considerable part of the dose passes unabsorbed in most conditions of the stomach and intestines. The loss of weight is an early sign of improvement; but it sometimes goes beyond the requirements of health, which fact suggests that under certain conditions, the thyroid secretion may modify the tissue changes even of healthy persons. Immediately after the injections, and even after the stomach doses, of thyroid, there is sometimes a rise of temperature and pulse, increased secretion of urine, faintness or headache, and other symptoms; as the treatment goes on these symptoms may continue for a time, and be associated with prostration, cardiac weakness, anginoid, neuralgic, or other pains, and even albuminuria. It is striking that these unpleasant signs sometimes continue for weeks after the suspension of treatment.

The paper contains the report of a case observed by the author and an exhaustive discussion of the subject of myxœdema in which the literature of the subject is very thoroughly investigated.

**Chloroma and its Relation to Leukæmia**

is the title of a paper by Dr. George Dock. The case observed by the author raises the number of reported cases to seventeen. In all cases the most obvious point in common is the peculiar color of the morbid growths found, which suggested the name chloroma or cancer vert. In the author's own case the color could best be described as pea-green. It differed, however, in various parts, so that some were pale sage-green, others darker, or again with pink, brown or red stains. The small growths in the liver and kidneys were almost white, but in the pancreas and thymus the color was distinctly green, though pale. The color gradually faded from the preserved specimens. Owing to the fact that the solutions were frequently changed, it is impossible to tell whether the color was dissolved out or bleached. The cause of the color still remains unknown. The external surface of the tumors were smooth or nodular—tumors proper, as distinguished from uniform infiltrations, being usually nodular. In regard to the seat of these growths: In all cases reported some part of the head was affected. Less frequently we find the green substance in the periosteum of the vertebræ and ribs adjoining. The marked predilection of the periosteum, especially that of the head, has been noticed by all observers, and most of them look on some part of the periosteum of the head or face as the starting point. The new growths are sarcomatous, in the sense that they are "connective tissue formations, with excessive development of the cellular elements." For the present, the author thinks we cannot do better than to use the term "Chloroma" in describing these tumors and some synonym, as lymphoma, lymph-adenoma, lympho-sarcoma, or myeloma, could be used to express peculiar features or the views of the reporter.

Chloroma is most frequently in early life—the average age of fifteen cases being 15–26 years. The course of the disease is short. The average duration, in twelve cases in which it is given, is five months. Exciting causes are rarely given in the reported cases. In one case the disease began with toothache, and the disease first appeared in the site of the extracted tooth. The fact that three cases were observed in Prague, three in Glasgow, and two in Paris seems worth noting. The family and previous histories were usually good.

The important points in the diagnosis are: The appearance, usually below the age of twenty, of anæmia without evident cause, with loss of strength, dyspnœa and emaciation; hemorrhages in skin, mucous membranes (epistaxis) or internal organs (retina); rapid pulse; ocular symptoms, such as difficulty of vision, strabismus and especially exophthalmus, without the special features of Basedow's disease and with tumor in the orbit; deafness and ringing in the ears; tumors under the temporals or on the cranium in other parts, or in other parts of the body. Before the appearance of the tumors the diagnosis would be doubtful, but after the appearance of tumors in the orbit and under the temporals it could be made almost with certainty.

In such cases the blood should be examined by all the methods known, either to detect an increase or alteration of the leucocytes already present, or, if that be not found, examinations should be made at short intervals in order to observe the possible event of a leukæmic condition, which might come on only a short time before death. The spleen, liver, lymph glands and bones should be examined with reference to alteration in size and tenderness. The literature of the subject is thoroughly discussed in the article which is illustrated with a portrait of the

patient whose case is described and also a colored print of the microscopical appearance of the blood.

Dr. Douglas Graham contributes a paper on

**Massage in Muscular Rheumatism, and its Possible Value in the Diagnosis of Muscular Rheumatism from Neuritis.**

The author ventures the suggestion that when a case of apparent muscular rheumatism does not only not yield but also does not stay improved after massages, then the probability is that the case is one of neuritis affecting the nerve fibres that supply the impaired muscles. This probability would be strengthened when the pain is uniform, affecting the same muscles on both sides, when it is worse at night whilst the patient is at rest and warm in bed, and better when up, moving about, which calls into play the inhibitory action of the will; whereas muscular rheumatism is aggravated by motion and relieved by rest and warmth. The difference in favor of neuritis would be increased when the consistence of the affected muscles does not differ from that of the well muscles or is somewhat diminished.

The relief from discomfort, and freedom of motion experienced after each massage, in those cases which are too apt to be snappily diagnosed as muscular rheumatism, but most likely are neuritis, is so great that, though the temporary improvement may not be held, yet the patient is apt to demand that the massage be continued until the ultimate result, which, with appropriate internal medication, should be recovery.

**The Anatomy of the Vermiform Appendix**

Is discussed by Dr. A. Hewson in a paper on the subject. In his researches the author examined seventy-four subjects. In twenty-eight subjects the most frequent position for the appendix in relation to the ileum was below and behind, remaining in the false pelvis. The next most frequent was below the ileum, remaining in the false pelvis.

In sixteen subjects it was either below and behind the ileum in the cavity of the true pelvis and in the remaining eight was either below or behind the ileum and above the innominate crest, i. e., not in the false pelvis even. In fifty-seven subjects the position of the appendix was on the inner and posterior aspects of the colon, and in the order and number of frequency—inner, eight; posterior, six; and inferior, two. The average distance from the anterior superior spine of the ileum to the base of the appendix was 7.2 cm. The average measurement from the anterior superior spine of the ileum to the apex of the appendix was 8.3 cm. The average distance from the umbilicus to the base of the appendix was 8.1 cm. The average distance from the umbilicus to the apex of the vermiform appendix was 10.1 cm. The great variation in the amount of mesentery belonging to the appendix leads the author to the conclusion that one must always expect to find the mesentery extending more than one-half the length of the appendix, and that from its free extremity one must expect great latitude of position—which may be assumed both on account of its length and also on account of the manner in which its mesentery is attached.

Dr. Charles J. Foote presents the "Report of a Case of Grangrenous Stomatitis, with a Bacteriological Examination."

Dr. John K. Mitchell presents the report of "A Case of Local Catalepsy," the left hand being affected. The author states that he is unable to find the report of a similar case.

## THERAPEUTICS.

### Poisoning with Turpentine.

Carvete (*Canadian Practitioner*) has reported the case of a woman who at bedtime, took half an ounce of old spirit of turpentine mixed with an ounce of whiskey, in mistake for castor oil. The mistake was only noticed after the turpentine had been swallowed, but nothing was done at the time except to take a dose of castor oil. The patient shortly afterward fell asleep, but was awakened in the course of five hours with sickness of stomach. A little later she vomited, and after the lapse of several hours more she had a convulsion, followed by loss of consciousness. The pulse was weak, feeble, rapid; the face and lips pale; the patient restless, at times delirious and talking incoherently, but capable of deing partly roused. Urine had been passed in generous quantity. Whiskey, spirit of nitrous ether, milk, and sweet oil were given, and warmth was applied to the body. Vomiting was induced by irritating the fauces. The vomited matters had a strong odor of turpentine ten hours after the fluid had been taken. After free vomiting, consciousness was regained and complaint was made of a burning pain in the right leg. Examination disclosed the presence upon the posterior aspect of the knee of a blister 5 by 12 inches in extent, the contents of which were watery and emitted an odor of turpentine. Gangrene of the superficial parts took place in this area, and fifteen weeks elapsed before the resulting ulcer healed.

### Therapeutic Effect.

This interests the physician, who is desirous of establishing a reputation for success; interests the pharmacist, who desires to establish the confidence of the physician in the remedies furnished, and interests the patient, who is anxious to make a speedy recovery.

IT IS OFTEN A DISAPPOINTMENT.

1. Because the patient does not follow directions.
2. Because drugs cannot benefit the case.
3. Because the dosage is incorrect.
4. Because a wrong remedy is selected.
5. The remedy is deficient in strength or is over active.
6. The vices or habits of the patient neutralize or abort treatment.—*Phar. Era.*

## MEDICINE.

### Parotiditis Complicated by Orchitis, Prostatitis, and Hemoptysis.

Comby (*L'Union Medicale*) has reported the case of a gardener, twenty-nine years old, who, after having worked all day in a hot house, was seized at night with a chill; the right testicle was noted to be swollen, red, heavy and painful. During the night there occurred sweats, with headache, pain in the back and in the extremities, so that sleep was prevented. There was also evidence of the existence of a mild prostatitis. On the following day delirium set in, and a day later still painful swellings appeared in both parotid regions. There were fever and dyspnea, and in the midst of a paroxysm of coughing, profuse hemoptysis occurred. Improvement now soon set in and in a short time the man was convalescent. Examination of the chest failed to disclose evidence of organic disease; neither did the urine present any abnormality. The treatment employed consisted in the administration of quinine sulphate, purgation, the application of emollient compresses to the testicles, and a milk diet.

### Peculiar Symptoms in an Infant Due to Contracted Prepuce.

Dr. S. E. Moses, reports a case of an infant, two months old, weak and delicate, who was suffering from an attack of whooping cough, was suddenly one night attacked by what was described as inward convulsions. I sought the aid of Dr. Crombie, and on enquiry found that the child generally cried before passing urine, and that the so-called fits came on every two hours or so. Our attention was drawn, therefore, to the urinary organs, and we found a long tight prepuce with a pin-point opening. We were fortunate, for while we were examining the child, a fit came on. There was no convulsive twitchings nor spasms of any kind; on the contrary the child lay limp and lifeless; the respiration stopped, and we had to resort to artificial breathing for some time before the infant breathed, and then it came in gasps for some minutes till eventually the respiration became normal. The heart beats were 20 in the minute, and gradually as the respiration returned they rose to 120. The lips were livid, the eyes fixed and not sensitive to touch. The child passed urine and the fit shortly after wore off. I watched the child in several such attacks—some lasting 15 to 20 and 26 minutes. Dr. Crombie and I gave strychnine, but without effect, so on the following day we decided upon slitting up the foreskin, which we did, and no fit such as described has again returned. I would wish in this case to point out the crying of the child before the passing of water, the regularity of the return of fits every two hours, the time the bladder took to fill: and the passing of water before the fit wore off, and the immediate cessation of fits after the operation.—*Indian Med. Gaz.*

### How to Give a Fomentation.

Doubtless every physician knows how to apply a fomentation, yet the following suggestions may be of value to some one (*Jour. Bact.*): A flannel cloth may be folded, wrung out of hot water, and applied directly to the skin; nevertheless, it is much better, after wringing out the flannel as dry as desired, to fold it in a dry flannel cloth of one or two thicknesses before applying it to the patient. A little time is required for the heat of the fomentation to penetrate the dry flannel, and thus the skin is allowed an opportunity to acquire tolerance for the heat, and a greater degree of temperature can be borne than if the moist cloth is brought directly in contact with the surface. The outer fold of dry flannel will also serve to keep the cloth warm by preventing evaporation.

A fomentation is sometimes needed when no hot water is at hand. It is not necessary to wait for water to be heated in the usual way. Soak the flannel in cold water, wring as dry as desired, fold in a newspaper, and lay upon the stove or wrap it about the stovepipe. In a few minutes it will be as warm as the patient can bear. The paper keeps the pipe from becoming moistened by the wet flannel, and at the same time prevents the flannel from being soiled by contact with the pipe.

Fomentations thoroughly applied will relieve most of the local pains for which liniments, lotions and poultices are generally applied, and are greatly to be preferred to these remedies, since they are cleaner and aid nature more effectually in restoring the injured parts to a sound condition.

## ARMY AND NAVY.

U. S. ARMY FROM JULY 30, 1893, TO AUGUST 5, 1893.

Major Alfred A. Woodhull, Surgeon U. S. Army, is granted leave of absence for one month and fifteen days, on account of sickness, to take effect on or about August 15th, 1893.

Leave of absence for two months, to take effect about August 10th, 1893, is granted Captain Edward C. Carter, Assistant Surgeon U. S. Army.

Captain Walter D. McCaw, Assistant Surgeon, is relieved from duty at Camp Pilot Butte, Wyoming, and ordered to the Presidio of San Francisco, California, for duty.

## NATURAL AND ARTIFICIAL DRYNESS IN CHAMPAGNE.

Natural dryness and the smallest percentage of alcohol constitute the purest and most wholesome champagne, as compared with artificial and spirituous dryness, which admits of a higher percentage of sugar in the wine, while giving a dryer but false taste, as is the case with several of the so-called "brut" wines. By chemical analysis of Prof. R. Ogden Doremus, G. H. Mumm's Extra Dry contains, in a marked degree, less alcohol than other prominent brands, and he recommends it, not only for its purity, but as the most wholesome champagne.

*Bonfort's Circular*, the authorized organ of the wine trade, of January 10, 1893, says: "Custom house statistics for 1892 show G. H. Mumm & Co.'s Extra Dry far ahead of all its competitors, its importation asggregating 75,880 cases, being more than one-fifth of all combined, and over 9,000 cases more than any other brand. While words tell, statistics prove, and the best evidence for unexcelled quality, purity, natural dryness and wholesomeness that can be produced, is given by the success of this famous wine."

G. H. Mumm & Co.'s Extra Dry of the excellent vintage of 1889 is attracting great attention for its natural dryness, purity and quality.

### SOME NOTES AND SUGGESTIONS ON ASEPTIC AND ANTISEPTIC SURGERY OF THE PRESENT TIME.*

FRANKLIN STAPLES, M. D., Winona, Minn.

I am persuaded that the discoveries, the improvements in methods and material, and the work that has been done in this department constitutes the most important advance in the surgery of modern times; and this, not only because by its means and methods we are able to do old operations more successfully and with quicker and better results, but because new fields have been opened and a great number of life-saving operations in abdominal, thoracic and brain surgery, which before could not have been safely attempted, have been rendered possible and practicable; and, of no less importance is the fact that our means of diagnosis have been greatly increased. It is in the memory of some present, when to operate with great rapidity was regarded as evidence of the greatest skill in operative surgery. The introduction and the use of anæsthetics and the better knowledge of anatomy and pathology in later times, has done much to do away with this opinion. Being able now to take time in our work, and by means of our aseptic and antiseptic methods, to guard against the evil results which would otherwise follow and which formerly did follow our operations we are able to make explorations into organs and cavities throughout the body that in pre-antiseptic times could not be safely done. Thus it is that our means of better diagnosis have been greatly enlarged, and much that is new in pathology has come to our knowledge. The literature of this subject made within the last quarter of a century has come to be immense. It now has place in the standard works of this country and of the world, as well as in the medical and surgical periodicals of the day. The excellent practical work of Gerster, of New York, especially deserves attention and study.

Mr. Lister, of London, began to make known his work in 1865. W. Watson Cheyne, of London, whose article on "The Antiseptic Method of Treating Wounds," appears in the *International Encyclopædia of Surgery* by Ashurst, says, that for several years previously he (Lister) had been impressed with the great evils which resulted from the putrefaction of discharges in wounds, and, though he had in many ways succeeded in lessening the occurrence of putrefaction, yet it was not until after he had examined the results of Pasteur's researches on spontaneous generation and on the causes of putrefaction, that he was able to systematize his work.

Up to the time of Pasteur there seem to have been two opinions, especially among English pathologists, as to the causes of putrefaction or fermentation, so called, in the fluids on diseased and injured surfaces and in the tissues of the living body, viz.: first, that this process of change was due to the effect of *the*

*Read before the Southern Minnesota Medical Association, August 3, 1893.

*gases of the atmosphere* upon the organic fluids after their exit from the tissues and after they had lost their vitality; and second, that the changes of putrefaction were due to the spontaneous alteration in the fluids and tissues without the intervention of any extraneous cause. Various attempts were made, especially by French surgeons, to prevent or lessen the process of putrefaction and suppuration, and thereby secure a union in wounds by what was called "first intention," by mechanical means for excluding the gases of the air from the injured or affected parts. All these attempts were in a great measure failures, not being founded upon a true pathology. Most of us remember the days of plasters and salves and all kinds of lotions used in the dressings of wounds. Time went on and progress was made. A single quotation from the article of W. Watson Cheyne shows among other things, the beginnings of carbolic acid.

While these attempts to prevent putrefaction by excluding the "gases of the air" were being made, indeed before they had been thought of, it had been found that the addition of various substances to organic fluids, whether outside of the body or in wounds, had a marked effect in retarding or preventing fermentation, and notably in preventing smell. These substances, therefore, received the name of "antiseptics" substances which prevented putrefaction, or, literally, which acted against the causes of putrefaction. These had been in use for a long time, chiefly in the form of various balsams, ointments, and lotions. The most efficatious balsams contained various essential oils, which we now know to be powerful antiseptics; while the best lotions had, among other substances, alcohol as their chief component. The treatment of wounds with antiseptics had, however, been carried on in a very desultory manner and without any fixed guiding principle, until the publication in 1859, of a paper by Corne and Demeaux on a paste containing coal tar. By means of this paper, the attention of French surgeons was at once attracted to the whole question of the use of antiseptics in the treatment of wounds, and for a year or two very fertile results were obtained. Lemaire more especially took the matter up, and after experimenting with an emulsion of coal tar with very good results, he at length found that carbolic acid was the chief constituent of coal tar, and accordingly introduced it into practice. During the same time various other antiseptics were brought forward, of which alcohol, in the practice of M. Nelaton, yielded the most important results. As a result of Lemaire's writings, the use of carbolic acid spread very rapidly on the continent, and even in Great Britain a few surgeons, Spence, Wood and others, employed it somewhat extensively. Carbolic acid as used in this way has however, many disadvantages, and hence many who had at first employed it largely gave it up almost entirely, and it seemed likely to fall into disuse, until it was again brought into notice by the writings of Lister."

We well remember the opposition that was made to what was called Listerism. It was in the comparatively early days of scientific study and work in bacteriology. It was then an easy thing for speakers and writers to sneer at the germ theory of disease, and to laugh at the means and methods of the germicide treatment. Even at the present time these objectors are unfortunately not all dead. It may not be counted to the credit of any professional man of science who, because there were imperfections in the early teachings and work in antiseptic surgery that further knowledge and experience had to correct, instead of doing honest and intelligent work in the way of clearing up the difficulties and finding the truth, did what he could to keep up the number of objectors and to retard scientific progress.

There are different classes of men who are always found on the back side of the wheel of progress. First: There are those who, by their mental and moral make-up, are naturally inclined to say no to whatever is first suggested or advocated by any one save themselves. Unfortunately there are, and always have been, men prominent in the profession who have manifested this spirit. Some seem ambitious to acquire distinction as wise critics and objectors. We have heard of men who were willing to commit murder and take the consequences for the sake of notoriety. Second: There are those who, even in surgery, are too busy even in their own way, or are too ignorant or indolent to keep abreast of the times. To be able to do and to do well in

any department of science, requires intelligent observation, hard work and self-sacrifice. Third: There is another class, somewhat related to the class just described, which seem to hold that, in order to succeed in a financial way in the practice of medicine and surgery, all expense must be reduced to the minimum. It is not the policy or practice to any great extent, to buy books, take journals, or buy instruments and surgical material, such as are now required for good work in surgery, gynecology or obstetrics. Practitioners of this class are not likely to make their influence felt in the literature of the profession, nor are they in the way of doing much in the work of educating the race.

The old idea that decomposition and putrefaction were due to the gases of the atmosphere alone, or to the spontaneous generation of disease germs and the development of the same in the tissues themselves, was shown to be incorrect by the observations and experiments of Mr. Tyndall especially, and to his observations is largely due the better knowledge and work of the present day. I have recently read Dr. H. Gradle's book on "The Germ Theory of Disease," written ten years ago, and have been greatly interested in his clear and concise presentation of the subject of the germ theory as it bears upon practical medicine and surgery of to-day. After describing Tyndall's methods of removing from a certain portion of confined air all particles of foreign substance found to be floating in it, Dr. Gradle says, "In the most elegant manner did Tyndall show that this optically pure air, identical with the surrounding air but deprived of its dust, could not produce decomposition. Test tubes had been let into the bottom of air-tight cases from which all floating dust had been removed, and were filled through a moveable pipette perforating a rubber diaphragm in the top of the case, the entrance of the pipette being protected by a packing of cotton. After filling the glasses with various putrescible substances and plugging the pipette, they were sterilized by five minutes' boiling. Though exposed to the air in the box, these organic solutions kept sweet indefinitely, while a second set of test tubes similarly treated, were teeming with life and most offensive in smell after a few days' exposure to the impure air of the laboratory. Are not these various experiments complete proof of the role of atmospheric dust as a cause of putrefaction? Is there a link wanting in the chain of evidence that the air cannot by itself start decomposition, but that it contains floating particles, living dust, which on reaching the proper soil develop into the organisms whose life-work reveals itself in putrefaction." Our present practice of excluding, so far as possible, from our operating rooms and hospital wards all dust-making and dust-holding material, and of adopting such means as may prevent the diffusion of infecting germs from the bodies and clothing of operators, assistants and nurses, is based upon this doctrine, viz: that the germs of putrefaction in surgical injuries may be and are oftener than otherwise introduced in this way from without.

In these times of aseptic and antiseptic surgery we have learned many things, and are in the way to learn many more, and already we have had time to demonstrate the practical advantage of what we have learned. We have learned something of what the operating room should be, the advantage of the clean uncovered floor, the plain walls, the plain metal or polished wooden furniture, the plain dishes and trays for solutions and for holding instruments and material when in use. We have learned the use of hot water as a germicide. We have learned how much it means to take care of instruments and hands and the bodies and clothing of operators and attendants, in order that all may be entirely aseptic at the time of work. We have learned something about the necessary temperature in the operating room, especially when the great cavities are to be opened. We have learned what are the particular uses of the cat-gut, the silk worm gut, and silver wire, and how to make them and keep them aseptic. We have learned something about irrigating septic wounds, and of the various solutions for doing this work. We have learned something about carbolic acid, bichloride of mercury, iodoform, and other articles of like character. We have learned something of the dangers of impure sponges, and that there may be death on the hands and under the finger nails in obstetrical cases, in surgical gynecology and in laparotomies. We have learned to appreciate the services of a clean and faithful nurse, who keeps herself aseptic in body and clothing.

Dr. John A. Wyeth, of New York, in his recent excellent work on general surgery, devotes his first chapter to surgical dressings, ligatures, sutures, irrigating solutions, etc. This chapter, indeed the whole book, should be read by every practicing surgeon. I have here a few practical notes from the same.

*Sutures and Ligatures.*—Silk, cat-gut, silk-worm gut, and silver wire will meet every requirement in tying vessels and closing wounds. Silk is the invaluable suture material. The finest black iron dyed silk is needed in plastic surgery especially of the neck and face. Cat-gut should be kept in well closed jars made for the purpose, with the material completely covered with the pure oil of juniper. Ninety-five per cent. of alcohol is equally aseptic and is well adapted to the silk. Twisted silk is better than the braid.

*Solutions.*—For irrigating wounds, submerging instruments, and disinfecting in general, solutions of corrosive sublimate and carbolic acid are necessary, and pure alcohol, iodoform and chloride of zinc solutions may at times be used.

Koch has demonstrated that, as a germ killer, corrosive sublimate excels all known agents. The sublimate solutions vary in the proportion of one part of the bichloride to five hundred parts of distilled water by weight, or 1 to 500, 1 to 1,000, 1 to 2,000, 1 to 3,000 for use outside of the great cavities, and 1 to 8,000, 1 to 10,000, 1 to 15,000, and 1 to 20,000 within the cavities.

The sublimate solutions are only used for irrigation and for disinfecting the hands, sponges and gauze. All instruments are submerged in carbolic acid solutions or in alcohol.

The steam and carbolic spray, formerly used during an operation, has been abandoned for the purpose for which it was used, and is now only used to lay the dust or as an aid toward the more thorough cleansing of operating rooms and wards.

It is unnecessary for me to speak at length of the various kinds of material and apparatus now used in good antiseptic work. Surgeons have in daily use and understand the comparative value of iodoform, aristol, chloride of zinc, carbolized gauze, sublimate gauze, iodoform gauze, borated absorbent cotton, and the protectives of rubber tissue, oiled silk, and Mackintosh rubber cloth. The making and the care of the different drainage materials come in as an important part of the work. The essential of aseptic surgery is absolute cleanliness. This means vastly more than most people are able to understand. It applies to the body of the patient and to all surroundings, the substance of which or the emanations from which, may come in contact with the parts under treatment. Dry heat and hot water are important means. While asepsis is the first essential, to secure this condition antiseptic means and materials, such as have been enumerated, are indispensible.

It is not alone in the greater operations that asepsis and antisepsis have been found of great importance. In general practice in minor surgery we are able to have results which a few years ago were thought to be impossible. In lacerated flesh wounds and crushed limbs and extremities, such as we have in railroad coupling accidents for instance, good practice is as follows: After carefully cleaning the lacerations throughout their extent and judiciously trimming and removing the parts of flesh and bone that have been actually destroyed, thoroughly irrigating, then bringing the torn and cut parts together with aseptic sutures if necessary, dusting any denuded surfaces and along the line of the sutures with the iodoform or aristol powder, enveloping the whole with antiseptic gauze and with the rubber protective and bandage, and taking care that absolute rest shall be had and a proper temperature maintained, we allow days before a redressing is done. At the end of from four to six days and sometimes more, upon removing the dressings, we are apt to find a kind of parboiled condition of the skin, no redness, no swelling, no inflammation, no suppuration. This experience is in contrast with what used to be, for parts are saved and rendered useful which formerly were sacrificed, and the chances of general septicæmia are greatly lessened.

Many practitoners who are compelled to do more or less surgery, generally in emergencies and frequently in the country under unfavorable circumstances, may be inclined to say that these teachings are all very well and that the principles of practice are probably correct, but to do work in the manner required is impossible ex-

cept in the well furnished operating rooms of modern hospitals, or at least in the cities where the means can be had and qualified nurses may be employed, and the practical conclusion is that it is useless to try. This is wrong. Let the surgeon thus situated make greater efforts to overcome, so far as possible, the difficulties with which he has to contend. Let him not fail to keep himself supplied with the best material required in first-class work and be diligent in learning how to take care of it and how to use it. Let his practice in the details of aseptic and antiseptic surgery not only enable him to secure good results, but be a means of education to the people with whom he has to do. In this connection and in closing I have a brief note or two from Gerster.

"Unremitting attention to, and a severe self-dicipline in always carrying out the measures of strict cleanliness known to be necessary to uniform success in the management of wounds, will gradually become, however irksome in the beginning, a mere matter of accustomed routine. As the mind and senses learn to exercise vigilance without special effort, the surgeon's results will become more and more gratifying.

"It is a great mistake, paid for by the loss of limbs and lives, to believe that the mastery of practical cleanliness, or asepticism, can be acquired without a clear comprehension of the principle, and without earnest and severe training in the handicraft of asepticism.

"The school of learning to employ the principles of asepticism is open to every general practitioner, in the treatment of many affections and injuries pertaining to minor surgery.

"Emergencies will necessarily involve varying modifications of the means, but never a deviation from the principle of asepticism.

"A hasty tracheotomy for the removal of a foreign body, a herniotomy to be done in the dead of the night amid the squalid surroundings of a tenement, or the first care of a common fracture or a gun-shot wound, will present special and varying difficulties, to be overcome only by good training, circumspection, and versatility. They can be overcome, as many examples in the experience of every successful surgeon testify."

In taking account of the present and rejoicing in the achivemeuts of to-day, we should be glad to realize that we are in the way of progress which is still leading to a better and higher future.

# COMMUNICATIONS.

## BLOOD PRESSURE.*

WM. BAILEY, M. D., Louisville, Ky.

Recently attention has been directed to heart therapy, and to the influence of those remedies having direct power over the heart and circulation. Believing that influences exerted for circulation should extend much beyond this central organ, important as it may be, I ask attention to blood pressure.

Two factors are essential to the production and maintenance of tension. First, and perhaps chiefly, it is dependent upon the power of the heart. Next upon the size of the arterioles and capillaries.

Pressure is increased by whatever gives additional power to the heart, and it is diminished by whatever lessens the heart power. Pressure is increased likewise by whatever diminishes the size of the arterioles and capillaries, and it is diminished by whatever increases the calibre of these vessels.

Pressure is highest when the heart acts with vigor at the same time the vessels are contracted. Pressure is lowest when we have diminished heart power with dilated vessels. The work accomplished by the heart is dependent upon the size of the blood vessels more largely than often we recognize.

* Abstract of essay read before the Medico-Chirurgical Society of Louisville, Ky., July, 1893.

The heart, under no circumstances, can send into the aorta and its distributing branches more blood than it receives from the veins. Paralyze the veins and keep an animal in the erect position and very little blood reaches the heart, and in consequence very little is sent into the arteries.

A blow upon the abdomen of a frog will greatly distend the veins thereof, and a great difference in the pulse will be observed by changing the position of the frog from the perpendicular to the horizontal. The same thing occurs in shock or when one suddenly withdraws a large amount of ascitic fluid or urine from a patient in the erect position. This observation teaches us to place in the horizontal position patients under these circumstances, and even to lower the head below the level in fainting.

Nutrition takes place while the blood is in transit through the arteries and capillaries and not after it has reached the veins; hence it is largely dependent upon the size of these vessels. Although a vital process, it depends upon the passage of nutrient material into the tissues through the vessel wall; after serving its purpose it is reabsorbed and passed on to the veins.

The forces concerned in securing the circulation of the blood are purely physical and obey well-known physical laws. We can gain valuable lessons as to the circulation of the blood by studying the circulation of water through the pipes and hose attached to our water mains. The height of the reservoir and the size of the delivery pipe determines the character of the flow.

It has been demonstrated that the veins are capable of holding more blood than an animal possesses; that the entire volume of blood of an animal may be introduced into the veins of another animal of the same size, without increasing tension, provided section of the medulla oblongata has previously been made. The influence of the vaso-motor centres is at least the equivalent of the ordinary volume of blood in maintaining blood tension. In other words, blood tension is better maintained under normal action of the vaso-motor system than it would be without it, even if twice the ordinary volume was furnished.

Tension in the arterial system depends upon the volume of blood sent into the aorta, the force with which it is pumped and the more or less readiness with which it is allowed to make its exit through the capillaries into the veins.

To insure good work on the part of the heart it is necessary to have a healthy organ and an abundance of good blood at its disposal. Sufficient time should be allowed it for filling its cavities, and too much hindrance in its delivery not offered it. Time will not allow me to consider fully the nerve supply of this central organ. It is well-known that the heart depends upon the nerve forces governing it for the character of the work it will perform, and the especial purpose of this paper is to ask more earnest attention to blood tension as affecting the purposes it is endeavoring to accomplish. The character of the pulse should have closest scrutiny in order to facilitate the work to be done. It may be that we will thus find that the heart is fully able and abundantly willing to perform its duty, but is handicapped by difficulties placed in its way by the condition of the capillary circulation. It will be observed frequently that the heart is laboring vigorously and impatiently with over-distended cavities due directly to abnormal contraction of the capillaries, and rational medication requires us to lessen this tension rather than to further goad on a willing heart.

I admit that with our present imperfect knowledge some very difficult problems present themselves to us in the use of remedies for influencing the circulation of the blood, but we will not be aided in their solution by *blindly* using, as is the custom with some, such remedies, so potent for both good and evil, as digitalis.

Fallacies easily creep in when we begin to study the physiological action of drugs, but there are many earnest and competent workers in this department of medicine and the hope for the future is very bright. The greatest need of medicine to-day, is knowledge of the natural history of disease, and accurate knowledge of the physiological action of drugs. The day is passed for blind, haphazzard prescription writing.

I shall not undertake to even mention the names of the drugs that might be considered in connection with this subject for my sole purpose is to suggest a line of thought for discussion but, as most apt, I would ask you to consider the physiological action of digitalis and of the nitrites.

# STONE IN THE BLADDER WITH A REPORT OF CASES.*

FLOYD WILCOX McRAE, M. D., Atlanta, Ga.

In treating of this subject, I shall speak succinctly of the etiology, symptomatology and treatment of stone in the bladder, purposely avoiding extensive details and references to authorities.

The chief predisposing causes—defective digestion and assimilation due to improper diet, to a preponderance of solid over liquid ingesta, or to high living coupled with insufficient exercise and imperfect oxidation. Whatever the cause, there is always an excess of the solids of the urine. These, however, are only predisposing causes, and colloids as mucus, pus, etc., due to inflammatory conditions of the urinary mucous membrane, must be present before stone in the bladder will result. Constitutional vices, such as gout and rheumatism, and the allied condition lithæmia, are important causative factors. Enlarged prostate and stricture of the urethra, with the inflammatory changes resulting therefrom, act as immediate causative factors in a small proportion of cases. The extremes of life present the larger number of cases. Males are much more frequently affected than females. The children of the poor are more subject to vesical calculi than those of the wealthy, because improper and insufficient diet and insalubrious surroundings bring about that condition of the system most favorable to the development of stone, just as we have the same conditions resulting from excessive indulgence in rich food and alcoholic beverages, coupled with insufficient exercise in the other extreme of life in the wealthier classes.

The large majority of calculi are composed of either uric acid or phosphates. The former predominate in children, and the latter in the aged. Renal calculi, foreign bodies, etc., passing into the bladder, act as nuclei and grow by accretion of urinary salts. In not a few cases the development of stone in the bladder will have been preceded by the descent of a renal calculus with its concomitant symptoms. A history of nephritic colic not followed by the expulsion of the gravel through the urethra, would naturally lead us to suspect the formation of stone in the bladder when there is subsequent irritation of that viscus.

Frequent urination, worse during the day than at night, increased by exercise, is one of the earliest symptoms. This is, in the majority of cases, accompanied by pain of a gnawing, burning character referable to the end of the penis, and which is relieved by pulling the prepuce or pressing the glans. Children thus not infrequently acquire the habit of masturbation. Boys with stone in the bladder very frequently present elongated and irritated prepuces, brought about by constant traction for the relief of the pain. Sudden stoppage of the stream during micturition—due to a small calculus having engaged in the neck of the bladder—is another of the earlier and more important symptoms. This condition is frequently relieved by change of position, so that the victim of stone in the bladder soon learns in what position the urine may be passed with the least pain and voids the urine in that position. Hæmaturia is also a symptom of some importance, especially if only present at the end of micturition and accompanied by other symptoms. Reflex pains, especially persistent podalgia, are often significant symptoms. Priapism, mucopus in the urine, etc., are of minor importance.

None of the symptoms thus far enumerated are pathognomonic of stone in the bladder Only when the stone can be felt by the searcher and the characteristic click elicted are we sure of the presence of a calculus in the bladder. Even then there are possible sources of error, such as the presence of incrustations and indurated growths. Nor is the failure to find the stone with a searcher proof that one does not exist. There are several sources of error here also, viz; a small stone behind an enlarged prostate, encysted stone, or stone contained in a diverticulum. Thus it is clearly seen that in a certain small proportion of cases, the surgeon finds it difficult to know just how to proceed. Whether it is better to operate in the face of a probable failure to find a stone, or to let the

*Read before the Georgia State Medical Association, May, 1893.

patient suffer till the suffering becomes unbearable, or a positive diagnosis may be made, is a question by which the surgeon is sometimes confronted. Where, however, the discomfort is great it seems to me it is better to operate, for usually when a stone is not found other conditions obtain that are susceptible of operative relief.

In one of the cases which I shall report further on, the symptoms were characteristic of stone in the bladder, although no stone was found. The operation, however, was a brilliant success in relieving the patient of a most violent cystitis of long standing.

In stone in the bladder, just as in most other diseased conditions, each case is a law unto itself, and must be treated on general surgical principles. The operator who wisely determines as to the best method of procedure in each individual case, other things being equal, will get the best results. Of first importance is the prophylactic treatment, i. e., the treatment of lithæmia in its various manifestations including renal calculi. Also the treatment of those obstructive and inflammatory conditions which are such important factors. As already stated, in the formation of stone I have only mentioned the prophylactic treatment, with no intention of entering upon the consideration of this interesting and important part of the subject. I have intended in this paper to discuss only the surgical treatment of stone in the bladder. Of all the methods of treating stone in the bladder none has so wide a range of applicability and so low a death rate as litholapaxy (Bigelow's operation). I have, however, had no personal experience with it, as the cases thus far presenting themselves to me were such as seemed to me were more amenable to other procedures. This operation offers much the best results except in very young children, very large or very hard stones, or where there is co-existing tight organic stricture, or enlarged prostate of such character as to prevent the introduction of the lithotrite, or where there is a violent cystitis due to the presence of a stone. For large stones associated with prostatic or vesical tumors, the high operation is undoubtedly far superior to any perineal operation. Small stones associated with stricture of the deep urethra or violent cystitis are best treated by the median operation. Nor is the lateral operation to be entirely set aside for the now more popular operations of litholapaxy and supra-pubic lithotomy. Each of these operations has its proper field of usefulness, and it is only by a careful selection of the methods of treatment that the best results are to be obtained.

Case I. Mr. F., æt. 72 years. Fat, fleshy, very flabby; weight about 200 lbs. History of bladder trouble extending over a period of five years, during which time had had two attacks of left hemiplegia. Marked cystitis existed, for which various internal and vesical injections had been used with little effect. Large quantity of pus and mucus in urine associated with blood, the latter being greatly increased by exercise. Constant felling of weight in bladder and occasional violent pains, spasmodic in character, and aggravated by locomotion. No relief from treatment. Sounding bladder failed to demonstrate the presence of stone. Operation undertaken at the urgent and frequent solicitation of patient and friends. Supra-pubic cystotomy decided upon. Operation August, 1890, assisted by Drs. V. O. Hardon and L. P. Kennedy; chloroform anæsthesia. Large phosphatic calculus (weight about 800 grs.) removed. Operation completed in usual way. Patient's condition excellent; rallied promptly from anæsthesia; no vomiting. Drainage excellent. No unfavorable symptoms until morning of 5th day, when deep coma suddenly supervened, and death resulted a few hours later. Temperature never rose above 101° F. No post-mortem. Wound in very healthy condition. Death probably due to cerebral hemorrhage.

Case II. S. M., æt. 2 years. Well nourished. History of "gravel." One small gravel removed by attending physician from fossa navicularis, a few weeks prior to operation. Retention of urine.

Operation May, 1891, assisted by Drs. L. P. Stephens, L. P. Kennedy, L. B. Grandy, and C. C. Johnson. Chloroform anæsthesia. Meatus enlarged and five small phosphatic calculi removed from anterior urethra. Sound arrested by calculus impacted in prostatic urethra. Decided upon left lateral operation, which was immediately done. Large quantity of phosphatic debris removed from bladder. No well formed calculi—so soft that they were crushed as soon as grasped by forceps. Bladder thoroughly irrigated. Sub-

sequent history uneventful. Recovery perfect. No return of trouble.

Case III. Negro, æt. 61; blacksmith; weight 190 lbs. General condition good. Characteristic history of stone in the bladder. Operation Dalton, Ga., November, 1891, assisted by Drs. Gordon, Bivins, and McAfee of Dalton, and Warren of Atlanta. Left lateral operation; difficult on account of depth of perineum. Medium sized phosphatic stone removed entire. Weight 300 grs. Recovery excellent. No recurrence. Time of operation including sounding and dressing, 20 minutes. Enlarged prostate freely incised to make sufficient opening to allow removal of stone.

Case IV. J. D., æt. 28, St. Agustine, Fla. Vigorous. History of bladder trouble for over six months. Subjective symptoms characteristic of stone; urine full of pus and mucus. Sounding failed to elicit characteristic click, though slight grating was distinctly felt. Operation, Atlanta Medical College, February 13, 1892. Median operation. Large quantity of pus and phosphatic debris removed; bladder irrigated. No stone. Perineal drainage for ten days. Bladder irrigated twice daily with hot boric acid solution, or Thiersch's solution. Recovery perfect.

In the cases reported, I have simply stated, in the most concise manner, the histories of the cases and the results of the operation. Case I. was a forlorn hope. The probability of a good result was so remote that I should not have operated, notwithstanding the importuning of the patient and his friends. In cases II, III and IV the results were very gratifying indeed. All made excellent recoveries, are still living, and the relief afforded by the operations seems to have been complete and permanent.

# SOCIETY REPORTS.

## THE LOUISVILLE CLINICAL SOCIETY.

*Stated Meeting, May 16, 1893.*

The President, Dr. I. N. Bloom, in the Chair.

### DISCHARGE OF PUS AT THE NAVEL FOLLOWING AN ATTACK OF TYPHOID FEVER.

Dr. A. M. Vance: I saw a few days ago a little girl nine years of age, with the history that thirteen weeks ago she was taken with typhoid fever; according to Dr. Rudell who is the family physician, this disease ran a typical course up to seven weeks when the umbilicus became tender, not very red but pouted a little, and about two weeks afterward a small opening occurred and a great deal of pus was discharged. The doctor treated it expectantly for four or five weeks, up to the time I saw the patient last Friday. I advised exploration and more thorough drainage. The child was in an extreme condition, having emaciated almost to the last degree, was suffering with hectic fever and was in a very forlorn condition in every way. I was afraid to give chloroform but had to do so to perform an abdominal section. An incision was rapidly made in the median line using the umbilicus for the center, and a great quantity of pus was evacuated along with solid material which I thought at the time might be fecal matter. The pus was very fecal in odor. I found the abdominal wall from the ribs to the ilium had entirely separated from the parietal peritoneum and this surface was suppurating from the opening back to the kidney region on either side. I passed my hand around on each side to discover, if possible, the source of this abscess, but could not find any perforation. The whole area was thoroughly washed out and stuffed with strips of iodoform gauze on each side. Since then the child has been very much better, eating constantly, calling for food, sleeping well, and has been very much more comfortable. To-day I found that the gauze would not drain well toward the umbilicus and I made counter openings as far around as I could reach with a probe and put in two large rubber drainage tubes to either side

from the umbilicus. Drainage has been perfect since. I believe the trouble was due to a perforation of the intestine at a point where there was an adhesion to the parietal peritoneum and the pus seeking a point where there was the least resistance, finally discharging at the navel, where there possibly was a little hernial weakening.

I have never seen a case just like it; it is something new in my experience and I thought a report of it might be of interest to some of the fellows. I am convinced that there was a fecal opening somewhere, probably in the right iliac region.

DISCUSSION.

Dr. J. G. Cecil: Dr. Vance's remarks recall to my mind a case of typhoid fever in a colored woman in the City Hospital, that had a perforation of the gut; but it was never diagnosticated, nor suspected until after death and the post mortem revealed the true state of affairs. In that case we found evidences of general peritonitis but more particularly in the region of the cæcum and small intestine; wherever we found Peyer's glands there was localized peritonitis, with an accumulation of fecal matter, pus, etc. of a very offensive character. I was particularly interested at that time to know that a case of typhoid fever might suffer a perforation and yet not give any of the classic signs, sufficient at least to lead to a diagnosis. I am sorry that I cannot recall more correctly the exact facts in the case. The patient lived probably several days after the time we supposed this perforation took place. Of course not knowing that there was a perforation we could not ascertain to a certainty when it did occur but, after recalling the history of the case, it being substantiated at the post mortem, we thought probably it occurred several days before death.

The case related by Dr. Vance seems to me to be a very extreme one; he suggested the other day in private conversation that it must have been due to a perforation, and from the history of the case I do not see how there can be any other rational explanation of it.

---

ABDOMINAL PAIN FOLLOWING TYPHOID FEVER.

Dr. J. M. Mathews: A young lady consulted me to-day with the following history: She is about twenty-one years of age and had an attack of typhoid fever eight months ago in the city of New York. She said that the attack was accompanied with several very distinct and large hemorrhages from the bowels; that after she made a recovery she felt a pain which was aggravated upon exercise—going up stairs or anything of that kind—continually; that she was forced to use even now an abdominal supporter; that she consulted her physician who was an eminent physician in New York, and he told her that with this history of typhoid fever accompanied with hemorrhages and with this pain that she evidently had extensive adhesions and warned her that should she have an acute attack at any time, to immediately consult a surgeon, because an operation would be necessary. The reason she consulted me was that she states if she goes one day without an evacuation this pain is set up with great intensity and she has to at once open her bowels with an aperient.

On questioning, and with a partial examination of the case, I found that she referred the pain nearly directly to the McBurney point and she gives the history of having had several distinct attacks of pain, which would indicate more or less appendicitis, and I was inclined to think, or, at least the question arose in my mind, whether or not it was not separate and distinct from her attack of typhoid fever, in other words outside of Peyer's patches; whether or not the appendix was involved, having no connection with the attack of typhoid fever. She is impressed that she will possibly need a surgical operation as she has been warned that this might be the case.

DISCUSSION.

Dr. Wm. Bailey: Basing the idea of perforation upon fecal odor: Is it not possible, owing to the thinness of these structures, to have a fecal odor without perforation?

Dr. A. M. Vance: Yes, I think this is quite possible, and may have been the cause of the fecal odor in the case I reported, but there was considerable material looking like fecal matter in the right iliac fossa. There is one point I failed to mention in the history: I gave the child a purgative the day after the operation and she had several large evacuations, and my attention was called to the peculiar

character of them, looking like they were filled with thousands of little bodies; the whole mass seemed to be filled with little worms. I could not make out what it was at first, but finally came to the conclusion that it was the little fibres of banana that go from the center to the periphery of the banana. The child had eaten a great quantity of bananas even the day before the operation.

---

CONTINUED REPORT—INTUBATION FOR PAPILLOMA OF LARYNX.

DR. WM. CHEATHAM: I want to make a continued report of a case of intubation; a child about three and a half years old which I had to tube for papilloma of the larynx, making pressure and thus hoping to produce absorption. The child has worn the tube since September last, having been changed three times in the meantime. The father telephoned me the other day that the child had coughed the tube out, and I asked him to bring the child to my office. He did so and gave me the history that the child dropped in the back yard as if in shock, and the mother found the tube partially out and pushed it back; I found the tube in position, but turned half around. Could not get it out with the extractors. I had to milk it out by putting my right fore finger in his mouth and placing left thumb below tube on larynx by firm pressure up and back. I finally succeeded in getting it out. This was last Monday and the child has not had to have the tube inserted since and the breathing has been perfect without it. It is marvelous how these little ones get used to the tube. In removing this tube I did not have to use a gag to hold the mouth open. He held his mouth open each time and allowed me to use the extractor without any trouble.

I have two cases on hand now of paralysis of the left recurrent laryngeal. One of them interested me a great deal in which there was at first paralysis of the recurrent laryngeal, which supplies the abductor and adductor and the arytenoid muscle. Some gentleman has taken this nerve and dissected the three fibres, showing them separately. This case had adductor paralysis at first, the cord being firmly contracted and drawn over to the left. He did not know what was the cause at first but later it has been found that he has an aneurism of the aorta. His voice was exceedingly bad, he was very hoarse, as is usually the case with adductor paralysis. In the last few days he has improved very much. Upon examination I found complete paralysis of the left vocal cord; it having taken the cadaveric position, the right cord now does not have to go over so far.

In the other case of paralysis of the left recurrent I have not yet been able to make out any cause. I have also a young lady with paralysis of the arytenoideus muscle, with loss of voice six months. I do not know whether it is a case of hysteria or not. She has menstrual trouble. I have not been able to find any local cause for the paralysis.

---

MILK SUPPLY OF LOUISVILLE.

DR. J. M. MATHEWS: I thought this evening would be an opportune time for a discussion upon the question of the milk supply of Louisville in connection with the epidemic of typhoid fever. There are two or three points that I would like to have the members consider.

First: Whether or not it is a recognized fact that water and milk are agents or vehicles for communicating the germ that produces typhoid fever.

Second: Whether there is a specific germ causing this disease, and if not how much do we know about the cause of typhoid fever in this connection?

Third: Recognizing that there has been an epidemic of typhoid fever in this city, whether or not the circumstances surrounding this epidemic and the investigation made by the State Board of Health was warranted.

Fourth: How should an examination of this kind be conducted?

We must all recognize that there has been and is now an epidemic of typhoid fever, as I say, in the city of Louisville. In one certain district, as Dr. Bailey will tell you, there are upwards of forty-five cases suffering from the disease who are or have been taking milk from one certain dairyman. I would like to hear an expression from the general practitioner and bacteriologists as to whether there is a suspicion correctly founded or not, and if so should it not have been investigated in the manner that it has? The reason that I have presented this questien to-night is

simply this: That the daily secular press of Louisville in its energetic, not to say sensational way, has brought the subject so prominently before the profession and the people that some impression should be made upon them that is scientific and correct. We know how easily the laity are led away by articles in the daily press and we also recognize the fact that if they are led away in the wrong direction, that it is possible it might create a great deal of harm. Not being a bacteriologist myself, nor a general practititioner of medicine, I leave it to the members of the Society to discuss this question. I would like to hear from Drs. Bailey and Vissman as to the proceedings up to date, because I find the profession of Louisville are greatly interested in this matter. We must, as physicians, be given credit for trying to take money out of our pockets; recognizing as we do the cause of typhoid fever, we go to work trying to prevent the cause, yet the press are disposed to make light of us sometimes in our effort to prevent the disease.

Dr. Wm. Bailey: I would like to say that I have no further report to make, as I have not pursued any further investigations since my report to the State Board of Health, which you were kind enough to adopt in the minutes of the last meeting in lieu of the remarks I made at that time.

## LOUISVILLE MEDICO-CHIRURGICAL SOCIETY.

*Stated Meeting, June 9th, 1893.*

The President, Dr. T. L. McDermott, in the Chair.

### SYPHILIS IGNORANS.

Dr. A. M. Vance: I first saw this gentleman two years ago, at which time he had a suppurating condition of the left elbow joint following incision of the joint by Dr. Sloan, of New Albany, Ind.; the patient also had a number of suppurating points about the body, one in each armpit and I think one upon the thigh. He was considerably more run down generally at that time than he is now, and I took it to be a case of syphilis ignorans, he not knowing of having any primary lesion. I put him upon anti-syphilitic treatment which was followed by no improvement. I then gave him a constructive line of treatment; this was followed by some improvement in his general health, but there was no change for the better in the suppurating condition. After about a year the right elbow became affected; the arm pits never healed and I then put him in the St. Joseph Infirmary and scraped out every place that was in a condition of suppuration or open. At that time the elbow was perfectly flail-like in its action, no power at all, but since the operation he has gotten considerable power. I have been very much interested in the case because I could not determine just what the diathesis was; I do not think it is tuberculous. I have always had the suspicion that it is specific, but there was no improvement under the usual active treatment by the various methods—mercury was given first, afterwards large doses of iodide of potassium. An immense amount of broken down material was scraped away, and there has been considerable improvement in the last year. At no time during this period has he been compelled to quit his work, except for two months when I advised him to quit and go to the country. There is absolutely no history on his part of a primary sore, and no history of tuberculosis in the family.

#### DISCUSSION.

Dr. E. R. Palmer: I do not think Dr. Vance's reasoning that because the patient is not emaciated is against the idea of tuberculous trouble. I often see tuberlous glands of the groin in persons of a lymphatic temperament, who are apparently well nourished and in robust health.

Dr. Wm. Bailey: Have the discharges ever been examined microscopically?

Dr. A. M. Vance: No.

Dr. T. L. McDermott: I have a case under observation at the present time, whether it is similar or dissimilar I cannot say. I have had two cases of multiple abscess, whether specific or non-specific I

do not know, one of which was extremely interesting. He had been treated by many of the most prominent physicians of Louisville, including Drs. Cowlings, Crow and Yandell. Dr. Frerick had made an incision and scraped out the abscesses, also removing several pieces of bone. This patient had abscesses upon different parts of the body at different times. I was taken to see this man and prescribed elixir iodo-bromid calcium Co., not with the idea, however, that it would particularly benefit him, as it was strictly a surgical case in which I was not interested. I was greatly surprised about two months afterward to see the patient get out of a buggy and hobble into my office on crutches after he had been in bed about a year; after he had been to Europe and consulted some of the most eminent surgeons there and spent a fortune in doctor's bills in his efforts to get relief. He continued to improve and eventually became entirely well, not having an abscess since. Whether there was any virtue in the medicine, or whether the time had simply come when nature had removed the cause of the trouble, I am unable to say.

I have another similar case now. Dr. Roberts has seen the patient with me and I am sorry he is not here to-night. Some of the joints have become ankylosed as the result of abscesses, and abscesses have also appeared in other parts of the body. We cannot find any specific history. I have put him upon the same medicine, and although he is an aged man and broken down, the abscesses are healing. In the first case I did not believe the abscesses due to hypodermic injections.

Dr. A. M. Cartledge: This does not have the appearance of tuberculous trouble to me, and I am not inclined to look upon it as tuberculous in character. I think it is probably syphilitic.

Dr. A. M. Vance: I saw the case Dr. McDermott speaks of (first case) and I think one reason the abscesses never healed was owing to the hypodermic injections given by one of the physicians who treated him; certainly the abscess I saw was due to an unclean hypodermic.

---

PATHOLOGICAL SPECIMENS — INCARCERATED TESTICLE—STRANGULATED HERNIA—OPERATION.

Dr. A. M. Vance: This specimen is a testicle removed some time ago; my reason for not reporting the case earlier is that I have not seen Dr. Irwin present at any of the recent meetings, and as he was connected with the case I have waited until he attended one of the meetings. The patient was a man sixty-two years of age; Irish, and a great many years ago, when he first came to this country, he gave the history of pain in the region of the right groin to Dr. Coleman Rogers, who advised him to wear a truss in anticipation of a hernia. Dr. Irwin was the attending physician in the case for some time prior to the incarceration of this hernia, which took place the day I was called. At eleven o'clock Dr. Irwin was called and found a large hernia of the right side descended and could discover this testicle in the lower portion of it. After some difficulty he reduced the whole mass and told the patient to hold his hand on the ring until he (the doctor) could go after a truss. When he returned a smaller mass was present at the site of the hernia which he could not reduce completely, though it seemed to be easy to make it less in bulk. I saw the patient the same night at eight o'clock. We put him to bed and advised rest until the next day. There were no active symptoms of strangulation or of obstruction at that time, and we advised him to call us in the night if he had any trouble. He was a very eccentric man and did not call us during the night, though we learned he complained of severe pain. We saw him at nine o'clock the next morning and from the aggravated symptoms we decided there was obstruction and advised immediate operation which was consented to, but he would not go to the Infirmary, insisting that the operation be performed at his home. We opened the sac and found nothing but serum in it, quite a quantity of fluid also came from the cavity through the hernial opening. I enlarged the opening, practically making a laparotomy of it, and found that a coil of intestine, probably eight or ten inches, was strangulated, the strangulation being produced by slipping of the gut through the opening between a band and the testicle. The testicle was in the abdomen with this coil of intestine. The intestine was quite red, though after relief of the constriction it returned to normal color. I removed the testicle and did a radical operation for the hernia. The man further showed his eccentricity by

driving away the attendants we placed over him until we could get a professional nurse, getting up and walking about the room, getting on a vessel and having an evacuation of the bowels, etc. On our next visit we found him in collapse and he died at midnight same day of the operation. I take it that owing to his having gotten up and moved about, the ligature slipped, when hemorrhage took place, or there was some other cause for the great shock, as the operation was very satisfactory and it seemed that the man had every chance of recovery. No post mortem was held.

---

INCARCERATED TESTICLE — HERNIA — OPERATION.

This testicle was removed from a boy ten years of age for a condition similar to the case just reported, without the strangulation. The testicle was removed and radical operation done for the hernia and the boy made a good recovery.

---

SARCOMA OF HEAD OF TIBIA—AMPUTATION.

Here is a very interesting specimen to me. The patient was a girl about fifteen years of age; a robust healthy looking subject, who had the first symptom of trouble about the knee joint March 1st, last. I saw her a week ago with Dr. Krim. There was a large tumor occupying the inner side of the leg beginning at the epiphiseal line of the tibia and extending down several inches, with history of having rapidly grown. There was no elevation of temperature and the only trouble experienced was pain of an acute character; there was no fluctuation in the tumor. I was of the opinion that it was a rapidly growing sarcoma of the head of the tibia, and advised an incision and if this was proven to be the case, or if there were other conditions to prevent conservative treatment, to amputate. After some procrastination incision was consented to, Dr. Yandell having seen the case in the meantime and agreed with me in the procedure. I made an incision and found the periosteal structures very thick, the bone completely denuded, and the whole interior occupied by a soft mushy mass. This thinning out had taken place so thoroughly that spontaneous rupture of the tibia might have occurred without any great effort. After removing the mass and finding that the tibia was involved for fully six inches, I amputated the leg just above the knee. Patient has done well since the operation. Microscopical examination (by Dr. Frank) proves the trouble to be large round cell sarcoma.

---

REMOVAL OF BREAST FOR TUBERCULOUS CONDITION.

The last specimen is the breast of a woman twenty-five years of age, which I removed for tuberculous condition. She gave birth to a child two years ago and an abscess occurred and has remained open constantly; that is, whenever one opening would close it would re-open at another nodule, irrespective of the former sinus. You will notice that there are a number of nodules occupying the breast. Recovery has been uneventful except that the patient had secondary hemorrhage.

DISCUSSION.

Dr. J. W. Irwin: Referring to the first case reported by Dr. Vance: I think it is proper I should make a statement, owing to some misunderstanding that has arisen as to the conditions which were operative in causing this man's death. (I refer to Mr. J. D. O'Leary). He was a rather singular gentlemen; he had been under my care six months for another trouble. Dr. Bailey saw him once in consultation with me while he was suffering from an affection of the bowels. I discovered two weeks before his death that he had a hernia and advised him to wear a truss. He would not be persuaded that a truss was necessary from the fact that he said he had had the hernia all his life and had never worn "one of those things"; that the hernia came out during the day and went in at night. I assured him that all forms of hernia were dangerous; that some time the bowel would come out and could not be replaced, that this was the rule. The hernia might come out a great many times and be reduced but would eventually come out once too often. He insisted that he would not wear a truss. When the rupture took place I cannot say, but it must have been the night before I saw him. I saw him at eleven o'clock the day before he died and discovered the hernial

protrusion. He was in great agony, with all the symptoms of gastric pain, etc. I found a protrusion the size of a double fist, a great part of which was serous. After considerable trouble I was able to reduce it completely, and after reduction he was entirely relieved of pain. I left him lying flat on his back on a couch and instructed him to hold his finger over the opening to prevent the bowels slipping out again, while I procured a proper truss. He still insisted that he would not wear a truss but I left to get one and soon afterward returned to learn that he had gotten up and walked about the room, removing his finger from the opening, when the hernia came out again, but not to the same extent as before. I found him again in great pain and tried to reduce the hernia, but it was impossible to do so the second time. I then suggested that Dr. Vance be called, which was done and we made another effort to reduce it. We finally came to the conclusion that the obstruction was due to a retained testicle in the canal preventing reduction. In fact the diagnosis made by Dr. Vance and myself was so accurate that after the operation we found exactly the condition existing that we had stated would be found. The operation I want to speak of as being one of the most cleanly and at the same time one of the most conservative that I have ever seen. It would be safe to say that Dr. Vance removed at least two feet of the intestine, or more, through the opening before he relieved the constriction. He made quite a large opening, really a laparotomy. I do not believe the patient lost in all over a half teaspoonful of blood, the operation was done so carefully and so well. The patient did well after the operation as long as he remained in bed, but tried to persuade all of us, even Father Brady, the Priest, that he did not need a nurse. He further said that he had decided not to allow a nurse to be employed, and that he knew what he was talking about and would show us that he would have his own way just as he had refused to go to the Infirmary to be operated upon. He afterward drove Dr. Rice away, who had been left there to nurse him for a short time, telling him, I believe, that he did not need his services any longer. Mr. Faulds was then allowed to remain with the patient until I could return with a trained nurse which I had been looking for and had in view. The patient in order to show that he did not need a trained nurse, got out of bed, had an evacation of the bowels and walked over to the window, sat down in a chair and looked out, went back to bed and soon after got up again. When we called at five o'clock or a little after, we found him, as Dr. Vance has said, in collapse, and ten minutes before twelve o'clock he died. There was nothing in the case, up to the time he got up and walked about, that would indicate anything else than that he would make a good recovery. I do not think his death was due to the operation at all, but believe it was due wholly to disobedience. I told the priest this at the time, and he agreed with me because he said the patient was a man self-willed; though gentle in his manner, he was determined to have his own way when he could. In this instance he did have his own way and he died.

Dr. A. M. Cartledge: The character of the obstruction makes the case a very interesting one to me. It only proves that in these old cases of hernia where there is an undescended testicle, it is impossible to tell the character of the obstruction until operation is performed.

The tibia case is also one of extreme interest. But for the microscopist's revelations I should be inclined to look upon the case as one of osteitis with its starting point at the head of the tibia. I believe that this, like a great many of cases we formerly looked upon as tuberculous, might be secondary osteitis grafted upon an osteo-sarcoma. In other words, the trouble being originally sarcomatous in character. We ought to have more of them examined by the microscope.

Dr. A. M. Vance: My idea of rapidly growing sarcoma was based upon the fact that the whole thing grew in three months; twelve weeks ago the patient was perfectly well, no fever, and while the pain was severe there was no evidence of fluid or breaking down. Very little fluid was found at the operation, and this was probably pus or some product of the sarcoma.

---

### PECULIAR CASE OF APPENDICITIS.

Dr. A. M. Cartledge: Last Tuesday evening at eight o'clock I was called to see a patient in consultation with a physician,

who gave the following short history of the case. Sunday morning he was called to see a boy who was taken with pain in the abdomen and diarrhœa, getting up very often, straining and having some small fecal evacuations; vomiting came on Sunday evening which he said was uncontrollable by all ordinary means. Sunday evening he concluded he would try ten grains of calomel; this quantity was given the patient which arrested the vomiting. On Monday morning he again visited the patient, some little nausea was present and slight tendency to vomit. He tried bismuth and carbonate of soda, etc., and during the day, Monday, he resorted again to the use of calomel with Dover's powder, which put the patient to rest again. On Monday three injections of water and glycerine were given which failed to move the bowels. Tuesday morning the temperature was 102° F., abdomen considerably swollen and he ordered some salts; vomiting continued, and another injection—a very high enema —was given without any result. On Tuesday evening he came to me with the statement that he had just left the patient with a pulse of 150, persistent vomiting with an incessant desire to get up and stool. I told him I thought it was a case of intussusception from the history given. I saw the patient about eight o'clock, found the abdomen greatly distended, pulse not as rapid as stated. I made it 132, and the boy's condition was indeed a very grave one. Vomiting was projectile and stercoraceous in character and I gave it as my opinion that it was probably a case of intussusception and advised immediate section. I returned to the city to get my instruments to do a laparotomy and at twelve o'clock the operation was performed. When the peritoneal sac was opened a great amount of fetid pus was evacuated; it welled up as soon as the incision was made and seemed to originate in the right iliac fossa. The intestines everywhere were matted together, and inflated with gas, each loop that came out showed evidence of adhesion to the loop that came in contact with it. Peritonitis was advanced. I found a mass in the right iliac fossa of considerable resistance, and upon drawing it up discovered that it was a portion of intestine constricted as though a band had been passed around it. After working in this region for some time I fished up this little enterolith, and soon found the vermiform appendix which had ruptured, showing that the original cause of the trouble was in the appendix. The appendix and this enterolith were carefully removed. Evidently the appendix had ruptured early in the attack and nature had thrown out a wall of lymph as a protection against infection of the general peritoneum; then this band of omentum had produced secondary obstruction as well as the original peritonitis. Several gallons of water were used in irrigation, and I determined if I had another case of diffuse advanced peritonitis I would put in three drainage tubes; one in the right iliac fossa, one in the left and another in the center. Three were used in this case, drainage was profuse. The patient was placed in bed in fairly good condition, but died the following day at twelve o'clock. I think the case an interesting one, illustrating another phase of the appendicitis subject. It seems that there is a never ceasing line of complications in these cases. Here was a typical history of intussusception, barring the tumor, which we were unable to discover owing to the tympanites, when the facts in the case prove it to be appendicitis with rupture and an enterolith in the cavity.

APPENDICITIS.

This is another vermiform appendix removed from a patient about the same age as the one just reported; operation done eight weeks ago. The patient was thought to have typhoid fever; he had a well defined tumor in the right iliac fossa. I operated without opening the peritoneal cavity and found about half a teacupful of pus. The cavity felt quite smooth at first, but in putting my hand down to the bottom of the pus cavity, I found the appendix and discovered that it had ruptured, the opening being a very small one. I made a little traction on it, passed a ligature around and tied it off. The boy made an uninterrupted recovery and was on the streets in twelve days entirely well.

AMPUTATION OF LEG.

Here is a specimen of extreme interest to me, being some blood vessels removed yesterday afternoon. Dr. Vance assisted in the operation. I was called yesterday afternoon to see a young German of power-

ful physique with this history: Last Monday while at work throwing beer kegs upon his wagon, he was seized with numbness of the right leg, almost unable to stand up, and suffered with burning sensations in the bottom of his feet. A physician was called and thought it was paralysis, and he was treated with this idea until I saw him yesterday. I found a German about twenty four years of age of enormous physical development; the leg was cold and lifeless from about 4½ inches below the popliteal space down, no circulation at all; there was already discoloration and evidences of gangrene taking place. The posterior surface of the leg had a peculiar feeling, indicating possible rupture of the tibial. I examined the heart and it was a peculiar one. No valvular murmur could be detected, yet it was a very restless and irritable heart. There were no evidences of fever; temperature 99°F. There were no indications of a rheumatic condition of the heart, though he gave the history of having suffered a severe attack of rheumatism in early life. From the fact that gangrene had already begun, and the apparent lifeless condition of the limb, it was amputated between the knee joint and the thigh. We found very little blood even after the Esmarch was removed. Another strange thing was that the femorals did not pulsate either before or after operation. After getting the patient to bed, Dr. Vance and myself opened the leg posteriorly, and found just at the junction of the tibials a thrombus, although in slitting up the vessels along the posterior part of the leg we did not find anything looking like an embolus, but just these little casts which had obstructed the posterior tibial. The vessels seemed to be thickened on that side and the question is whether it was an embolus from the heart primarily, or whether an endarteritis causing local thrombus. Another question is, owing to absence pulsation of the femoral, whether there is of not a higher obstruction in the vessel and the patient will have the same trouble further up. His temperature this morning was 102° F; to-night it is 100°F; pulse 88, and patient resting comfortably.

---

SECOND OPERATION FOR CARCINOMA OF THE BREAST.

The next specimen is a tumor of the breast removed to-day from a woman fifty-five years of age. One year ago this patient was operated upon for tumor of breast, and recurrence was very speedy in the line of incision. I take it that orignally there were no enlarged lymphatics in the axillary region, as the axilla was not opened at the orginal operation; in fact there was very little evidence of axillary enlargment, but at the operation to-day there were several enlarged glands in the axilla. I do not think all the gland was removed originally. In the operation to-day the axilla was thoroughly cleaned out and all suspicious tissue removed.

I report the case especially from the fact that I believe I removed more skin than I have taken out in the removal of any breast; nearly the whole of the pectoralis major muscle was removed, as it was all included in the tumor. So much skin was taken away that of course no effort could be made at approximation. I did insert a few sutures but the majority of the wound was left to heal by granulation and will have to be treated as an open wound. Dr. Vissman was present at the operation and with the microscope made several rapid sections of the skin in order to determine when sufficient was removed to get beyond the malignant trouble. This method is practiced largely in Germany and I believe the microscope can be used in this way to good advantage. The patient reacted very nicely, pulse 100 at close of the operation. The trouble was pronounced by Dr. Vissman carcinoma.

---

CONTINUED REPORT.—TUMOR IN EPIGASTRIC REGION.

Dr. A. M. Cartledge: You will remember this patient was before this Society about four weeks ago; was examined by several of the members present, on ac- of a tumor in the epigastric region. Several thought the trouble a distended gall bladder, others abscess of the liver. After making an examination at that time, I stated that I did not think it was abscess of the liver. The next day I made a further examination and came to the conclusion that it was a cyst of the pancreas. The day following I performed a laparotomy, following out the idea of pancreatic cyst, making my incision in the median line. After investigating through the incision, I found the case to be unquestion-

ably one of abscess of the liver and about a half gallon of pus was evacuated. I cleaned the cavity very thoroughly and inserted a very long drainage tube after packing the cavity with gauze. The patient has made an uninterrupted recovery; the liver is now about normal in size and the wound has closed with the exception of a very small sinus about a half inch deep.

---

J. Morrison Ray, M.D. then read a paper on

SOME DISEASES OF THE GRANDULAR TISSUES AT THE BASE OF THE TONGUE—SO-CALLED LINGUAL TONSIL.

Surrounding the upper respiratory passage is to be found a number of accumulations of grandular tissue to which have been given the name of tonsils.

Starting in the vault of the pharynx as an aggregation of lymphatic tissue, under the name of Suschka's gland or the pharyngeal tonsil, it extends on each side toward the orifice of the eustachian tubes, thence as a chain of submucous lymphatics down on each side to the space overlying the superior constrictor muscle, between the palato-glossus and palato-pharyngeus, the so-called pillars of the fauces, where it again becomes aggregated into the faucial tonsil. From these it extends down the lateral walls, between the divergence of the faucial pillars, toward the base of the tongue, where it again aggregates into lymphoid bodies that more or less fill the gloss-oepiglotidian fossa, and thus completes a grandular circle around the pharynx. Some have traced it still further, even into the ventrices of the larynx, where it may form a recognized enlargement.

The pharyngeal and faucial portion of this ring are found in their highest state of development in childhood, and, if they have never been the seat of inflammatory change, diminish in size as the age of puberty is attained, soon after which they disappear altogether, or present slight elevations marking the base of the original gland. That portion situated at the base of the tongue occupies the space behind the circumvallate papillæ, and in front of the attachment of the epiglottis. In the normal state it is observed best by the aid of the laryngeal mirror, yet I have encountered it so enlarged as to be seen by strong depression of the tongue, accompanied by efforts at gagging. With the laryngoscope this tissue appears as a number of elevations scattered in an irregular manner over the tongue, and extending over toward the lateral glosso-epiglotidian folds, with here and there veins of considerable size showing themselves as dark blue lines coursing between the lymphoid collections.

Unlike the faucial and pharyngeal enlargements of the lingual tonsil, it generally shows itself in adults. The cases I have seen were between nineteen and twenty years of age—the majority females.

Anatomically these glands are identical with the pharyngeal tonsil, consisting of accumulations of lymphatic tissue covered with mucous membrane, with here and there, on the summit of the elevation, depressions that mark the opening of the crypts or follicles. When excessively enlarged it represents two lateral masses, separated by the median raphe of the tongue, projecting forward so as to lie in contact with, or even overhang, the epiglottis. Generally, however, we see a number of masses irregularly placed. Within recent years considerable attention has been drawn to this region as the seat of annoying and often persistent discomfort.

Lennox Browne first called attention to a varicose condition of the veins in this locality, giving rise to symptoms of *globus histericus*. He states that there is frequently concomitant evidence of a varicose diathesis, such as rectal hemorrhoids, varicocele, or varicose veins of the extremities.

Rice and Curtis have reported cases of persistent cough and loss of the singing voice, due to hypertrophy of the glandular tissue. I have seen cases showing varicosity of the superficial veins in this locality, and a number presenting more or less enlargement of the glands. All such cases have not, however, presented symptoms referable to the part, and have improved without treatment of the base of the tongue. A few others I have seen wherein the condition was so very marked that the symptoms pointed so distinctly toward this region as the offending area as to make the indication for treatment unmistakable. The symptoms usually complained of are a sensation as if there was a foreign body present, with accumulations of excessive quantities of mucus and saliva and usually considerable cough.

These cases are frequently neurotic and dyspeptic subjects, who have been told they were suffering from catarrh or incipient phthisis.

I can best illustrate my subject by relating a few of the well-marked cases I have observed.

Mrs. R., age thirty-nine, wife of a minister from the southern part of the State, consulted me in 1891. She said that she had been told that her trouble was catarrhal, but her family feared tuberculosis, since a sister had died two years before, at about her age, with this disease. At the commencement her symptoms resembled those she had had for the past few months—these were a cough, a sense of fulness, with excessive saliva and constant desire to swallow, with a raw, burning sensation low down in the throat (this symptom she emphasized by placing her finger on the neck corresponding with the side of the larynx); her voice was husky, and easily fatigued; she suffered from constipation and dyspepsia, and attacks of eructations from the stomach. On examination the pharynx appeared red, congested, and contained a number of enlarged follicles, no enlargement between the faucial pillars; the nose and naso-pharynx were well open, and the turbinates gave no evidence of contact or pressure. The laryngeal mirror showed the larynx healthy. The lower pharynx was much congested and red; the base of the tongue presented a quantity of hypertrophied gland tissue; this was irregularly distributed—on one side a mass hid the epiglottis. The diagnosis I made was enlarged lingual tonsil, with pharyngitis, the latter probably due to the pyrosis.

I ordered a cleansing solution for use in the atomizer, and gave internally a laxative pill and lactopeptine, with bismuth. She left for home in a few days, feeling better. This continued for a short while, when I advised the use of dilute nitro-muriatic acid. Under this the regurgitation from the stomach was relieved, and the soreness in the throat disappeared. Two months later she returned, complaining of the fullness, cough, and excessive saliva. Skin being pressed, the pharyngeal redness was much less, but the base of the tongue still presented enlarged tissue. I determined on surgical interference. Painting the parts with a ten per cent. solution of cocaine, I removed several masses of gland tissue by means of curved scissors and a pair of post nasal cutting forceps. One piece that overhung the epiglottis was as large as a hazel nut. Some bleeding followed that was checked by hot water held in the mouth and allowed to be slowly swallowed. A few days later a few tags were noticed, making the surface rough; with the galvano cautery I destroyed these. The throat was very sore for several days, and I was unable to do more during her limited stay. I ordered a tannic acid and listerine gargle, and advised a continuance of the internal treatment. She wrote me about three weeks afterward that the soreness slowly disappeared, and with it the sensation of fullness and the accumulated saliva, and that the cough was better.

Mrs. X., age twenty-five. I saw her three weeks ago. (Her case suggested to me this paper). She complained of having been hoarse nearly all winter, and with it a disagreeable tickling sensation that caused much cough. Recently she had much family sickness and anxiety, since which the throat was worse, and felt full, with a constant desire to swallow. On examination the nose and upper pharynx looked comparatively well; the larynx showed thick, reddened cords; the inter-arytenoid space was roughened and covered with partially dried mucus; the base of the tongue showed three enlarged lymphoid bodies—one, the size of an almond, pressed firmly against the left edge of the epiglottis. I cauterized these well with galvano cautery, and ordered steam inhalation, and an alkaline solution for the atomizer, to be drawn well down into the larynx. I have not seen the patient since, but understand the throat was quite sore for a week, but since the voice has improved and the fulness in the throat is less.

These two cases are the only extreme ones I have met. An example of a less severe one is the following:

Miss M., age nineteen, was referred to me by a well-known vocal teacher of this city, with the statement that her head notes were bad, and her voice easily tired. The teacher had seen one case where I was able to improve the head notes by relieving a turbinated hypertrophy, and she suggested to this young lady that she probably had some nose trouble. On examination, the nose was found free of

hypertrophy or septal deflection, and the larynx was normal. I could, therefore, give no satisfactory explanation of her condition, but suggested treatment of the larynx by astringents with a brush, hoping that, by toning up the mucous membrane, an improvement would follow. On examination, preparatory to making an application of zinc chloride to the larynx, I noticed the base of the tongue. It appeared rougher than in health; a number of lymphatics appeared enlarged, and the mucous membrane congested. One gland was particularly enlarged, and the follicle on its surface contained a small whitish concretion. I decided to destroy this gland, and try treatment to this locality rather than to the larynx. I applied cocaine, and with the galvano cautery I destroyed this gland, the seat of chronic follicular disease. It was sore for only a few days. After this I applied, at three sittings, Lugol's solution and glycerine, after which the treatment was discontinued. Soon afterward I was informed that her voice had improved, and was not so easily fatigued.

I have treated a number of cases where the gland was more or less enlarged, without any improvement in the symptoms of which they complained. The three cases were reported for the purpose of showing the undoubted existence of a morbid condition in this locality that was remediable. I have had but little effect from alterative and astringent applications, and gargles do not reach to the locality.

I am convinced that cases do frequently occur, both of acute and chronic follicular disease, yet but slight reference can be found in literature to such a condition. I have recently encountered two cases of acute follicular inflammation of these glands—one, a negro, was in my dispensary service. The second case, Mr. G., had suffered for several days with some pain in swallowing, and it had been diagnosed rheumatic sore throat, and given anti-rheumatic treatment, but his throat had not improved. When I saw him there was no evidence of an acute process in the pharynx or fauces. On using the laryngeal mirror I noticed the base of the tongue on the left side was red, and covered with several follicular exudates.

The glosso-epiglotidean fold was edematous, and when the part was touched with a probe acute pain was elicited. Prompt recovery followed a few applications of iodo-tannin solution. There is no reason why these glands should not be subjected to the same forms of disease as affect the faucial and pharyngeal tonsil, such as accumulation of concretions, mycotic disease, etc., but they are often overlooked in searching for the cause of a throat trouble.

DISCUSSION.

Dr. S. G. Dabney: A great deal has been written in the last year in regard to the fourth tonsil. One of the most common symptoms of trouble in this locality is probably what is known as "empty swallowing" an inclination on the part of the patient to swallow when there is really nothing to swallow. I have seen a good many of these cases. I have one case just now in this city, a gentleman who has this condition in a very aggravated form, and who has recently been operated on for rectal hemorrhoids. My experience is that there is nothing better than the electro-cautery for the treatment of conditions of this kind. We often find dilated vessels with the glandular enlargement—a condition to which Lennox Browne has given the name of lingual hemorrhoids. There is one symptom I have seen often, which was not mentioned by Dr. Ray, and that is a little spitting of blood in the morning from the breaking of one of these enlarged vessels. Why it happens that this usually bursts during the night I do not know. In a recent number of the *Philadelphia Medical News* I reported several cases, one of which was especially interesting in this connection. It was that of a young lady who had long been troubled by cough and suffocative feeling, seeming to originate in the left side of her throat and occurring just after going to bed. Nose, naso-pharynx and larynx were normal, but at the base of the tongue and slightly catching the epiglottis was an enlargement of the glandular tissue. Destruction of this with electro-cautery gave entire and permanent relief from cough and other symptoms. In most cases of enlargement of the so-called lingual tonsil relief follows application of the electro-cautery and there is no return of the trouble. I do not think the local application of astringents are to be relied upon in such cases, if the hypertrophy is sufficient to cause any serious symptoms

my experience has been that little good can be accomplished by any local medication. I believe what holds true in so many parts of the body is applicable in cases of this character, that the affection in many persons gives rise to no unpleasant or serious symptoms, while in others very disagreeable effects are produced. This may be one reason why we see so many ladies suffering from affections of this nature, the same conditions in robust men not producing any disagreeable symptoms, that is not sufficiently marked to be noticable.

Dr. W. M. Cheatham: I have seen a great many cases of the character described by Dr. Ray in his paper. Concerning the question brought up by Dr. Dabney as to why so many slight hemorrhages occur during the night: Possibly it is owing to the fact that the blood vessels contract during the night. Theoretically we would suppose they would occur in the day time when the body is more active, the heart beating stronger and the blood being driven with more force, but my experience has been that the hemorrhages occur more frequently at night. I have used the galvano-cautery in the treatment of these conditions, and occasionally use a tonsillotome and sometimes scissors, but depend more upon iodine than anything else. When forceps or scissors cannot be used I resort to galvano-cautery. The symptoms are sometimes remarkably distressing, but are usually relieved a short time after the operation. My experience is that less inflammation follows the use of the galvano-cautery than any form of surgery. Indications for treatment here are about the same as in inflammation or hypertrophy of other tonsil tissue; at times local medicinial applications give relief, then again surgery alone is indicated.

Dr. C. Skinner: I would like to ask Dr. Ray if he has ever noticed that iodine used as a gynecological application had any effect upon the voice. The reason I ask the question is that last fall I treated a young lady, in the city, a professional singer, using iodine once or twice, and her voice did not get over the effects of it for two months.

Dr. J. M. Ray: I would say in reply to Dr. Skinner's question that we frequently find throat trouble to be the result of uterine disease. A well-known Philadelphia laryngologist claims to be able to look into the throat and diagnosticate various forms of displacement about the uterus by an examination of the larynx. The question of spitting blood, etc., was not mentioned in the paper because this symptom was not present in the cases I reported, although such a condition is often found and made a prominent diagnostic point by the text books. A point I wanted to make particularly in the paper was in regard to acute inflammation of this gland, you often find a condition resembling acute follicular inflammation of the faucial tonsil. I have seen several of them. Upon looking into the pharynx it appears to be in a healthy condition, yet the patients complained of persistent pain on swallowing. I have treated two or three such cases without thinking of the base of the tongue, and no relief has followed. In others I have treated the base of the tongue and found prompt relief. I believe that often cases of acute sore throat are really acute inflammations of the lingual tonsil. In fact I see no reason why acute follicular disease should not be as common in this locality as it is in the fauces and naso-pharynx.

---

An Unusual Case of Triplets.—The newspapers report a case of triplets in Nyack on the Hudson, which seems to be one of the most remarkable on record. There were two males and one female, and their aggregate weight was fifteen pounds. The two boys were bound together with a band almost precisely like that in the case of the Siamese twins, while the girl was joined to one of the boys by a band passing from the hip of the one to the hip of the other. The children survived for seven hours after birth. When the death of the girl and one boy had occurred an effort was made to save the life of the third child by cutting the ligature binding him to his brother, but it proved ineffectual.

---

Dermoid Cyst of the Lung.—A case is reported from Vienna, of a dermoid cyst of the lung. The tumor had its origin in the mediastinum, and after involving the lung ruptured into one of the bronchi, the hairs being coughed up in the expectoration.

# CORRESPONDENCE.

## To the Physicians of Pennsylvania.

Brethren in the Profession: I am a graduate of Jefferson Medical College, Class of 1890. I located in Noxen, a country town just springing into existence. There was no drug store within ten miles, consequently I was compelled to keep a large assortment of drugs for my own use. I soon developed what might be called a pretty well equipped country drug store which I operated in connection with my practice. I was arrested last June for violating the pharmacy law of this state and am under bail for one hundred dollars for appearance at court, August 14, 1893, at Tunkhannock, Pa. I had a training in the drug business with my father—who also kept a small drug store which he operated in connection with his practice—since I was fourteen years old. At the time the pharmacy law was passed in 1887, I was qualified as manager, which under Section VII, would entitle me to registration without an examination. After I graduated I applied to the board to be registered but they refused to register me, saying that if I wanted to continue in the drug business I would have to stand an examination before the Board of Pharmacy, or wait till I had practiced three years and apply under Section II. I continued right on with my business, expecting to register after I had practiced the three years. When the three years had expired I wrote again to be registered, but a reply came back very quickly that Section II had been repealed just two weeks before and the only way there was open for me was the examination. I complied with their request but was rejected. The Board from the beginning treated me with great disrespect. One of the members when he came to investigate, said to me when I met him at the depot and showed him all the courtesy I could, "We will go and see what kind of a ranch you keep."

I understand that the Board intends making this a test case.

I appeal to all my fellow graduates to aid me to make a defense.

Fraternally yours,

Noxen, Pa. G. H. Tibbins, M. D.

## Bromide of Potassium for Invagination.

Editor of Medical and Surgical Reporter:—The morning of March 10, 1889, I was summoned by Mr. S. who stated that his wife had suffered from colicky pains all night and was growing worse. The lady was aged 24, and four months pregnant; they supposed she would abort. In making examination I could readily distinguish a tumor in the region of the ileo-cæcal valve with other symptoms attendant upon invagination of the bowel. I gave her opium and belladonna. In the evening her condition was no better and I gave an enema of hot water but with no relief and continued the opium and belladonna. The next morning the patient was worse, showing considerable shock. As we were far removed from an abdominal surgeon, section could not be seriously considered. As bromide of potassum is one of our best antispasmodics, and as the disease under consideration unquestionably is of that class, I concluded to give it as a *dernier ressort*. I gave it in doses of ten grains once every hour, and in ten hours after giving the first dose the invagination was reduced.

I am well aware that a single case does not prove anything, but as bromide of potassium is the remedy *par-excellence* in certain forms of infantile colic, and as both diseases belong to the same class, viz, spasmodic, why should not the drug have a curative effect in intussusception if it has such action in its analogue? In my experience this valuable agent exerts almost a specific action on spasmodic diseases of the intestinal tract, and, with enough opium and belladonna to control deranged peristalsis, we have in bromide of potassium an invaluable medicine in all cases of invagination at all amenable to medicinal treatment.

The effect in this case was striking and unlooked for, and since in no text book can I find the salt mentioned as a remedy in this disease, I desire to give my happy result publicity throughly The Medical and Surgical Reporter.

ISSUED EVERY SATURDAY

ADDRESS
Care P. O. Box 843, Philadelphia.

HAROLD H. KYNETT, A. M., M. D.,
Editor.

RODERIC C. PENFIELD,
Publisher.

316 - 18 - 20 North Broad Street,
PHILADELPHIA.

TERMS:—Five Dollars a year, strictly in advance, unless otherwise specifically agreed upon. Sent three months on trial for $1.00.

REMITTANCES should be made payable only to the Publisher, and when in sums of Five Dollars or less, should be made by Postal Note, Money Order or Registered Letter.

NOTICE TO CONTRIBUTORS:—We are always glad to receive articles of value to the profession, and when used they will be paid for, or reprints supplied, as the author may elect. Where reprints are desired, writers are requested to make a note of that fact on the first page of the MS. It is well for contributors to enclose stamps for postage, that the articles may be returned if not found available.

SATURDAY, AUGUST 19TH, 1893.

## EDITORIAL.

### SPECIALISM IN MEDICINE.

The day has long gone by, never to return, when it was possible for one human intellect to master all that was known of medical science. As a necessary result of the increase of knowledge, medical literature has been divided and subdivided till there is no end to its ramifications. The old doctor,—physician, surgeon, obstetrician all combined in one—has gone, and in his place we have three practitioners, each with a special branch with which he is more familiar than his neighbor. Doubtless this has tended greatly to the increase of learning and to the physical welfare of mankind in general, but is there not a danger behind it all that has been creeping on so slowly that it has hardly been recognized as a danger at all? Is there not a tendency to enter into a specialty without the previous general training that should fit the man for the practice of that branch of medicine to which he is most drawn by his liking and tastes.

Perhaps this is most marked in that newest and most entrancing specialty, abdominal surgery. Allured by the brilliant results of a few operators and by the seeming simplicity of the operations, men have rushed into the field and proclaimed themselves masters of a division of surgery of which they knew little and into which they were drawn by the wave of enthusiasm with which the profession received this new offspring of medical science. Men, fresh from the college benches, with the newness of their diplomas still painfully apparent, have been tempted into the department of surgery that above all requires a cool head and a thorough mastery of all the resources of the surgeon's art. The result has been disastrous in many instances, lives have been lost or rendered unbearable from the untimely zeal and eager desire of these men to stand in the sacred temple of fame. Lured by the results of operators who have achieved their brilliancy as operators and their magnificent roll of lives saved on account of their long, painstaking years of work in this direction, these new comers have

entered regions that should have been holy to them and over which should have been written the legend "Noli me tangere."

The outcome of all this is easy to see. Any specialty into which men enter unprepared, must decline and lose its position among the handmaidens of medical science. In none of the branches of human arts or learning do men begin with as little practical knowledge as they do in a medical specialty. The young lawyer, fresh from his Blackstone, does not pose as an authority on the relations of landlord and tenant or become the great expounder of international law. He sits down quietly at his desk and watches the work of others who having been toiling at legal mysteries for years before him. Patiently, he goes on looking up points for some great legal battle in which the head of the office is engaged, gradually becoming more and more versed in the intricacies of his profession, till at last he can take his place among the chiefs of the legal army, and other young braves do the drugery that he has done for so long.

A man whose diploma proclaims greeting to all with whom he shall meet, and that the bearer has become very learned in the arts of mechanical engineering, enters the machine shops of a railroad. The officials do not greet him with "here comes a specialist, let us make him superintendent of motive power." He begins at the bottom, cutting threads on the bolts of the great machines that he hopes some day to have in his charge. Step by step he climbs through the grades of work in the shop till he stands as engineer on the foot board of one of those leviathans whose construction he has so laboriously assisted in. His college work has been taken only for its theoretical learning and not till he has mastered the whole practical part of his profession, from the thread on the smallest bolt to the maintaining of the fire that will supply motive power and the guiding of the locomotive through its daily task, is he fit to superintend the care of the company's motive power.

Thus will men do for the preserving of their legal rights and property, but when it comes to their lives they seem strangely indifferent. It remains for the doctor himself to fit himself for his duties. It is right that there should be specialists, but it is not right that they should be without the training that can be obtained only by a knowledge of general medicine and a careful preparation for their work by watching the work of the masters of their art. In our advance in the teaching of medical science we may have thrown overboard some things that are useful. The young practitioner of fifty years ago studied in his preceptor's office, and while he only got a narrow view of the practical side of medical work, he also got the method thoroughly drilled into his head. The modern student should study not only books, but men and methods. Let him choose an older man whom he will follow as a master and when he has become grounded in his master's specialty, then is he competent to stand before the people in the rank himself of a specialist.

---

Chronic alcoholism may be attended with symptoms resembling those of general paralysis, but the former are not progressive if the alcohol be withheld, while the latter, once manifested, continue to a fatal issue. The lesions of chronic alcoholism also most closely resemble those of general paralysis, but in one condition careful examination shows that the morbid changes fundamentally involve the intima of the vessels, while in the other it is especially the adventitia that suffers.

## SERUM-THERAPY AND THE TREATMENT OF TETANUS.†

Chouppe (*Le Bull. Med.* March 26,'93). says that since the first memorial of M. M. Behring and Kitasato in *Bull Med.* 1890, p. 1085, repeated attention has been given to the attempts that has been made to cure tetanus by injections of immunized animal serum. These attempts have thus far given negative or doubtful results. Behring and Kitasato argued that the blood of animals rendered immune to tetanus possessed the property of destroying the tetanic toxins and of vaccinating the animals against the disease. Shortly afterwards Behring confirmed the curative power of injections of antitoxic serum in mice already presenting decided symptoms of tetanus. This was the first attempt at the treatment. The vaccinating properities of the serum of immunized animals, its marked activity in destroying the toxins of tetanus when the serum and toxins are mixed either *in vitro*, or in the body of the animal, if injected simultaneously at the same point have been confirmed by several experimenters (Tizzoni and Cattani, Vaillard, Roux and Vaillard). This power, however, is of much less duration than Behring and Kitasato believe.

Behring and Kitasato had noted in their first memoir the possibility of curing tetanus already established by the injection of antitoxic serum. A little later, Kitasato confirmed these first conclusions by experiments on mice the subject of tetanus. These results, which were nothing less than the promise of a curative treatment of tetanus, were studied experimentally upon animals, at first by Vaillard who achieved only failure, and then by Tizzoni and Cattani who did not succeed any better. Moreover, the last experimenter noticed that the serum was not curative, even when the injection was practiced before the appearance of the tetanic symptoms, if, indeed, the injection was made only a few hours after the introduction of the toxin. Nevertheless, Kitasato pursued his researches, and in a new memoir he cited the results of the treatment of confirmed tetanus in mice. The result was as follows: A dozen mice were inoculated with a solution impregnated with tetanic spores. At the end of 35 hours all those animals presented the symptoms of tetanus. Two died tetanic 55 hours after inoculation. The other ten were treated by intra-peritoneal injections of antitoxic serum. Five of those died tetanic in 48 hours; the remaining five were cured. Behring on his side has published recently an article upon the experimental treatment of tetanus (*Dar Tetanusheilserum*, Leipsig, 1892); he has cured mice, sheep and a horse, in which tetanus had already developed before the commencement of the treatment. This shows the present status of the question. Roux and Vaillard have performed all of the experiments previously made, and a great many new ones, and their conclusions, which are nearly all negative, may be accepted. They have established the following point: when the antitoxic serum is injected long after the toxin or after the inoculation by the bacillus, so that lesions are already produced, it is unable to prevent a grave tetanus; if it succeeds it is only in the slight forms where cellular lesions are only tardily produced. But when the tetanic symptoms appear the nervous cells are already profoundly modified, and in their condition it is probable that the serum cannot be curative. In performing their experiments they have divided them into two classes: 1. Infection by the toxin; 2. infection by the spores deprived of the toxin. Whatever may be the mode of infection it is very difficult, they conclude, to cure an established tetanus in animals. When the first symptoms appear, the quantity of toxin elaborated is most often sufficient to slay the animal; it has acted upon the cells and the antitoxin cannot do anything to a poisoning already made.

A point to be borne in mind is that the subcutaneous injections of antitoxic serum have been entirely inoffensive in animals; all the probabilities are, therefore, that they will be also in man. In no instance can any bad effects be traced to the serum injectors. Kitasato made the first injection ever made in man. It was unsuccessful,

† Translated for THE MEDICAL AND SURGICAL REPORTER by W. A. N. Dorland, M.D.

because it may be that the case was a grave one and the treatment begun too late. Tizzoni and Cattani in Italy have employed the injections in eight cases, all followed by a cure (*Centrall. für Baklesiol. and Parasilink* Nov. 24 and 25, 1891). Their results, however, cannot be relied upon, since Albertoni claims that the cases treated and resulting in death were not published. Chouppe would conclude from his studies that bacteriologic researches relative to tetanus have not yet given an agent of an appreciable curative power in established tetanus. The only thing left to the physician is excision of the infected wound, and the use of nerve sedatives.

## EXTIRPATION OF A SPLEEN FOR TRAUMATISM.*

Reigner has reported a case of extirpation of an injured spleen following traumatism, (*Berlin Klin. Wöchen,* 1893, No. 8). He performed the operation on a boy aged fourteen. An outline of the history of the case would be of interest. On the day after the fall the pulse became gradually weakened; increasing pallor and dullness in the lower portion of the abdomen. The diagnosis was made as an intra-abdominal hemorrhage, necessitating an abdominal section.

On examining the interior of the abdomen there was found a transverse tear of the spleen of such dimensions that the lower portion was almost entirely separated and unconnected with the hilus of the spleen. The entire separation of the large blood vessels was regarded by Reigner as favorable, since the bleeding could only take place through one surface. The lower portion was at once separated and removed with other blood clots, the upper blood vessels and phrenicolineale ligament was speedily and thoroughly ligated. After a careful examination further injuries could not be found.

Healing of the wound and apparent entire recovery after twelve days; unfortunately gangrene set in through venous thrombosis, which made it necessary to perform an amputation four weeks later after the method of Gritti. Recovery seven weeks later.

This case was carefully watched by the author; seven months after the removal of the spleen he noted the patient's condition as good, the various functions seemed to perform their normal duties. The liver normal in size, but all external chains of the lymphatics are swollen; four weeks after the operation isolated glandular swellings were occasionally noticed; now after seven months isolated plexus, for instance in the axilla, were fonnd to diminish in size. The thyroid gland seemed enlarged. The medulla of the bone of the amputated limb shows a more active formation in the medulla than was to be expected. There had been an active increase in the blood vessels in the marrow of the bone, the canaliculi were contracted, the haversian canals were enlarged. The new marrow entered into the periosteum which could be seen distinctly by the naked eye, reminding one of the description given by Neumann and Mosler, as they had observed it in the animals upon which they had removed the spleen.

The examination of the blood showed that the increase or decrease of lymphocytes depended comparatively upon the glandular enlargement or contraction, and at the time of their decrease there was noted an increase of the polynucleated cells. There was nothing abnormal in the examination of the marrow other than active growth of the same. This was also affected by the variation of the glandular system.

Changes of the red blood corpuscles were never found; granular red blood cells, etc., were also absent. The author promises further communications upon this one very interesting case, as well as some experiments which he expects to perform on animals.—*Centrabl. für Chirurgie*, No. 23, 1893.

# ABSTRACTS.

## THE PATH OF IMPROVEMENT IN CANCER TREATMENT.

Dr. Herbert Snow, of London, in writing on this subject in the *Medical Press and Circular* says that: Cancer has long been regarded as the opprobrium of surgery, and I fear there is little doubt that the heroic new departures in surgical procedure of which we now not seldom read, will in the main rather intensify than lessen our reproach among men. Yet I cannot help thinking that were certain definite principles and axioms in the pathology, diagnosis, and treatment of malignant disease more clearly taught in the schools, and more accurately appreciated by the profession than has been hitherto the case, we should soon witness a corresponding improvement in results, an enhanced confidence on the part of the general public, with a proportionately less eager resort to the nostrums of quacks. I purpose here briefly to set for the a few of these:

1. *How does Cancer Kill?*—A complete reply to this question would involve a discussion of numerous technical details, which need not here be referred to. Sufficient for the present purpose it is to point out that, in those cases which especially claim the care of the surgeon, life is terminated much more often and in much greater degree by the metastatic offshoots than by the primary lesion, or by any consequences directly arising therefrom. That a malignant tumor thus more often kills indirectly than directly, by reason of the infective and autositic properties which its cell-elements have acquired, and by the ready transmission of these *per* the blood or lymph to distant parts. Of old the "recurrence" of cancer was attributed to its constitutional origin. That view has been dispelled by the advances of modern pathology, among which, by reason of its important practical bearings, I would take leave to mention my discovery of the insidious marrow-infection which accompanies ordinary breast-carcinoma. We now know that every species of cancerous neoplasm commences in a limited tissue area, whence contagious particles are transmitted by definite "infection-paths," which can nearly always be predicted.

From this principle may be deduced significant practical corollaries. First, that axiom upon which I conceive the future improvement of cancer-surgery most of all to hinge: of removing all the dangerous lymph-glands in the "infection-path" of a carcinoma or epithelioma, before they have had time to undergo increase in bulk. Thus the fatal progress of the infective lesion along its natural track is intercepted; and perchance complete extirpation may be effected. We should never attack an epitheliomatous tongue or lip, unless in a very advanced stage, without seeking also to remove the glands certain to be already infected, viz., those upon the anterior edge of the submaxillary serous gland, when the lip or fore-part of the tongue is diseased the cervical, opposite to the angle of the lower jaw, when the hinder regions of the tongue are first affected. We should only in rare cases excise a carcinomatous breast, without simultaneously evacuating the corresponding axilla. A melanotic or epithelial sore on the lower extremities or libia, should enjoin simultaneous attention to the surface lymph-glands in the inguinal region on the same side, and so on.

If, on the other hand, we wait until the lymph organs in question have undergone appreciable enlargement, we may be reasonably certain that the infection has already passed to other glands beyond our reach, and will eventually reappear (recur). Gland-enlargement is a relatively *late stage:* we have a previous one of tenderness merely, and before that of insidious deposit not attended by symptoms. Each of these in carcinoma lasts several weeks. Needless to point out that from the lymphatic system germs eventually reach the blood. To excise with the usual display a malignant primary tumor, when we neglect the secondary deposits which we know must have already ensued, is a sham operation, not a real one.

Again, it is commonly of more consequence to the individual to remove these secondary deposits than to take away the primary cancer, even when no more than immunity from future suffering, and transient prolongation of life can be hoped

for. The evacuation of the axilla with a breast carcinoma serves effectually to preclude that very distressing symptom "brawny œdema of the arm," due to lymph-stasis, combined with constriction of the axillary vein by a ring of cancerous parenchyma in the lymphatics. The suffering attendant upon neglected epithelial deposit in the cervical lymph glands of a physically vigorous man must be in every one's knowledge. The primary lesion of melanotic cancer of the integument (in the majority of instances, an epithelial disease generated in the deeper layers of the Malpighian rete) is commonly to the last a small ulcer or warty growth of the most insignificant dimensions. It can be radically extirpated, as a rule, without difficulty and without the least fear of local "recurrence," though too often the disease process is carried on to its fatal end by means of the previously infected lymph glands (see cases republished in "Cancers and Cancer Process," p. 365).

The routine operative treatment of cancers is greatly to be deprecated. Every single case should be scrupulously dealt with on its own merits, and not on any universal rule, with regard to numerous points of detail, such as the pathological species of the disease, the tissue this is most prone to infect, the idiosyncracies of the patient, etc.

*II.—Considerations on Early Diagnosis.*—It follows from the preceding that if we seek surgically to extirpate, that is to cure, cancer beyond the possibility of eventual re-growth, we must needs learn to recognize malignant disease, either before secondary infection has been established, or before it has advanced to any considerable distance from the site of origin. The diagnosis is easy enough when the lesion is of old standing, and is then practically useless; to be of real value, it must be effected in the incipient stage.

The subjective and objective signs, as laid down in ordinary text-books, pertain rather to the former period than to the latter, so are of but partial avail. What is really wanted is far greater stress than has hitherto been laid, on *à priori* considerations, so that we may be, as it were, on our guard against malignant processes, may know who is a likely subject for cancer, and who the reverse.

In the work above quoted I have attempted to constitute a novel group of cancerous neoplasms, derived from embryonic vestiges, not perfectly effaced. These, which I have termed blastomata, appear for the most part in childhood. They constitute a numerical minority of the total cancer cases, so do not affect the propositions here put forth in respect of the ordinary malignant disease of adults. Between these congenital neoplasms and the cancer of later life, there is a great pathological gulf fixed. With the exception of this anomalous and exceptional section, cancer is emphatically limited to persons who are growing old. Cancerous males are generally past forty; females with breast carcinoma are seldom younger than thirty-eight; those with uterine cancer, not often under thirty-four. The average cancer age is from thirty-eight to sixty years, and begins a few years sooner for women than for men. Thus persons who have attained this period of life are on that ground alone predisposed to malignancy. Heredity, it may be remarked, is an element which is much more likely to mislead in diagnosis than the reverse. In seventeen years' experience I have learned that a person who comes to me with a strong family history of cancer, is much more likely to be suffering from some innocent ailment than from this dreadful scourge.

The mammæ and uterus of women, and the mouth-cavity of men are the elective seats of malignancy in the two sexes, and derangements here apparent during the cancer age, therefore, demand special attention. People, male or female, who have undergone conspicuous impairment of general health, and loss of vitality from any cause whatever, are most liable to cancer-developments. The female organs referred to undergo a normal process of dissolution on obsolescence, and anything which interfers to hinder this is the fruitful parent of malignant growths. In this way mental anxiety and trouble are the common immediate forerunners of mammary and uterine carcinomata; so exhausting illness of any kind (I have known several cases immediately consequent upon influenza), specially toilsome occupations, such as that of the laundress, etc.

Such is the natural tendency in age, and in the degenerating female organs to

cancer, that after the thirty-eight years period, any tumor in the mammæ, whether previously noticed, or then appearing for the first time, becomes sooner or later associated with truly cancerous phenomena. Solid connective-tissue growths enclosing gland acine, adeno-fibroma, cystic fibroma are thus always of serious import. Even a simple cyst (sometimes a dilated duct, more often a dilated acinus), quiescent for some years, ends either by developing "intra-cystic vegetations" from its walls or by irritating the contiguous acini into malignant proliferation. These vegetations are most frequently carcinomatous, a less common form consists of embryonic connective-tissue (spindle-celled-sarcoma). A few are composed of well organized fibrous tissue, non-malignant, but always with a tendency to become more embryonic, and so sarcomatous. Thus it should be a maximim of the practical surgeon to regard every mammary neoplasm in an elderly woman as either an actual or a potential cancer.

Young people are particularly prone to lymph gland enlargement upon any slight provocation, most commonly of septic character; the old rarely suffer in this way. Thus any such feature after the age of forty, particularly when subsequent to mechanical violence, and when no septic cause can be detected in the vicinity, is strongly suggestive of primary malignancy in these organs (lympho-carcinoma). Both affections begin insidiously and painlessly. The latter is diffused very rapidly and is one of the most virulent of cancers. Should there be suspicion of malignancy, which, in an elderly person, must always be the case under the conditions mentioned, an exploratory incision should be performed with the least possible delay; thus alone can life be saved.

*III.—Importance of certain pathological considerations.*—The foremost consideration, from a practical point of view, is the escape of the adjoining lymph glands from infection per the lymphatic vessels, in true sarcoma, whereas in carcinoma and epithelioma, these organs very early become the seat of deposit. If, with a malignant growth developed from connective tissue corpuscles, we find glands in its vicinity enlarged, we know that there is general blood infection, and that metastases are also present in the vicera, consequently that an operation will have no curative efficacy. Hence in sarcoma, it is unnecessary to remove, as in carcinoma, the neighboring glands; and, if these be obviously attacked, it is generally best to decline operative interference altogether.

Unfortunately, however, a mischevious practice has crept in, of calling any acutely-growing malignant tumor of uncertain origin a "sarcoma," and thus that word has acquired a very vague signification. In the breast, soft cell-masses of encephaloid carcinoma are commonly so-styled; with these there is early axillary deposit, and the contents of the corresponding axilla need evacuation exactly as in the more chronic scirrhus, although the glands often do not exhibit much actual increase in bulk. On section these are gray, soft, pulpy, friable; the true sarcoma here is generally yellowish, its cut surface is fibrillated, and parts may be composed of well-organized fibrous tissue. The two species may generally be differentiated by the naked eye, with, of course, an appeal to the microscope later on. On the appearances disclosed by an incision immediately after removal do the further measures of operative procedure depend.

Symptoms of *marrow-infection* by breast carcinoma, particularly that which consists in a slowly-advancing prominence of the sternum in its junction with the second costal cartilage, necessarily indicate that amputation of the mamma can be palliative only. (For further details, see the work above quoted, p. 66).

*IV.—Palliative Operations.*—As a general rule it is unwise to attempt the excision of a malignant growth unless the whole of the palpable tumor can be removed; and unless there is good reason to anticipate prompt union of the wound. Cancerous parenchyma cut into, or otherwise irritated, will, as is well known, subsequently grow with greatly enhanced rapidity. Transgressions of this wholesome rule are largely accountable for the popular disfavor into which the surgery of cancer has fallen. The cases in which operative treatment is resorted to should be carefully selected; and there should be no indiscriminate resort to "the knife."

Valid exceptions, however, exist. The suffering by pain and starvation which tongue-epithelioma ultimately involves inculcate the extirpation of the organ at all hazards, even when some fragments

must of necessity be left. And sometimes there is such imminent risk of death from repeated hemorrhage, in the case of tumors elsewhere, that it is wise to attempt their partial removal.

Under all such circumstances, however, it will be well to eschew the knife for two reasons; one, that the patient is often very weak and cannot sustain the loss of blood which any cutting operation would involve; the other, that burning cancerous parenchyma checks its development instead of accelerating it. Even if the resulting wound does not heal, a chronic excavated ulcer will follow; not the exuberant fungous protuberance commonly seen after a measure of the former class. Thus, ablation of the tongue is effected without hemorrhage, shock, or risk by the galvanic écraseur. In other parts, a fungous bleeding mass may be shaved off, with much benefit the patient, by the same instrument, or by Paquelin's thermo-cautery.

*V. — Chemical Escharotics.* — Caustic applications in cancer are, of course, the great stronghold of quacks, who thus trade upon the fears of the timid. In carcinoma and the more severe forms of malignant disease they necessarily cause far more pain and shock than the usual methods of treatment. They can not, moreover, be had recourse to by the conscientious practitioner, on account of the principle pointed out at the commencement of this paper. It is the metastatic deposits in lymph glands and deeper tissues, that constitute the real *crux* of cancer surgery; we cannot apply chemical escharotics to deeply-seated glands.

In small superficial lesions, which are not associated with lymph-gland infection, such remedies are not absolutely barred, and may even possess distinct advantages. For in chronic epitheliomata, or rodent ulcers, they often answer admirably. The best is the stick potassa fusa, which acts rapidly and thoroughly, and whose operation may be instantaneously checked by contact with *water*. There is no subsequent pain or shock; the more fashionable zinc chloride is, however, conspicuous for the severe suffering which its use involves. Sometimes strong sulphuric acid in charcoal (or with asbestos, as in the notorious Michel's paste) may be resorted to for the purpose of destroying bleeding fungous granulations, but is apt to run over and injure the healthy parts. Its work can generally be done much better with Paquelin's cautery, Pastes of every kind are an abomination, slow, uncertain, painful, dangerous. The surgeon who has tried the potassa fusa will not seek any other caustic treatment of cancer.

*VI. —Medicinal Treatment.* —Making certain local exceptions, which must needs occur to every one, the golden rule in cancer not amenable to cure by surgical eradication, is to initiate at the earliest moment the administration of opium or morphia in small, continued, gradually-increased doses. The patient with an incurable maligmant tumor should thus become permanently subject to the morphia habit, purposely induced. The drug should be given with the avowed object of arresting and keeping in check the progress of the lesion.

The benefits of this principle are most evident in connection with carcinoma in the female breast, though by no means limited to this. If we are able to get the patient well under the influence of opium before ulceration has taken place, and the case be not of the acute type, we commonly see the organ pass into that atrophic, shrivelled condition of almost stationary disease, which causes no suffering, and is compatable with many years of comfortable existence. In uterine cancer, of which ulceration is a feature *ab initio*, considerable prolongation of life is effected, but not to so marked an extent as in the breast. The practice of withholding opium until compelled by pain to resort to its use, merits unmeasured condemnation from every point of view. Careful tending is imperative, and undue exertion should be avoided; an ulcer should never be permitted to become covered by an unsightly scab, or to emit an offensive smell; rest in bed should be encouraged. A patient who has been operated upon should, if possible, be kept under observation for at least two years subsequently. In any such believed to be liable to "recurrence," and particularly in women who display the peculiar physical signs of marrow-infection, treatment on the above plan should be instituted immediately after recovery. Humanely speaking, the path of improvement which I have here attempted imperfectly to indicate, would seem at present to lie far more in the better use of weapons long ready to our hand than in the discovery of new

# APPENDICITIS: WHAT IT IS AND WHAT IT IS NOT—FROM A SURGICAL STANDPOINT.

JOSEPH HOFFMAN, M.D., Philadelphia, Pa.

Among many with the fear of surgery before their eyes, there is a widespread and possibly a growing opinion that the advanced surgeon of to-day rushes upon every so-called case of appendicitis knife in hand, something after the manner in which our English friends fearfully dread the wild onslaught of the murderous Comanche in Chicago. To the surgeon holding in his mind the dangers and complexities of all serious abdominal work, most of all that in which the integrity of the vital organs is involved, the eagerness with which this operation is supposed to be sought is amusing. With those to whom the abdomen is as yet a fairyland of surgery, where reputation may be speedily got, and mistakes hastily veiled in the coroner's office by death from heart failure and exhaustion, the fair field is enticing. But woe to the untrained explorer who anchors his tray beside the siren, "Appendix," floating dreamily in a puddle of pus. The electricians are happier than he, and rather to be desired. With a view of insisting rather that surgery and surgeons shall not be held responsible for every vagary of the imagination by which operation is justified, whether cause exist or not, some of the determinate conditions and considerations belonging to the operation are here briefly presented. First of all, the anatomical relations of the appendix must be considered as settled finally within the peritoneum, and therefore, any inflammation of the organ is necessarily within the peritoneum; and inflammation outside the peritoneum, associated with the appendix, is the result of extension of the disease from within, outward. Advancing along in the anatomical conception of the disease, we must remember that no matter what the cause of irritation or inflammation in the organ, we must not expect a common symptomatology or a fixed locality by which the disease is infallibly to be recognized or located. This opinion, in view of the somewhat general belief in the McBurney point, must be explained anatomically. Elsewhere I have referred to the anatomy of the cæcum as insisted upon by Rokitansky, and a careful attention to a few points, *seriatim*, must convince the most skeptical, that although in a few cases the point of greatest pain in appendicitis may be constant, still there is no anatomical ground for this, and the cause is found rather in pathological adhesions in a given line than for any other reason. The cæcum hangs more or less free in the abdomen, and has therefore considerable latitude of motion. There is first, rotation upon its own axis; second, rotation upon the mesentery as an axis; and third, upon another intestine as an axis. By rotation upon its long axis, the cæcum may become so twisted that the ileum opens on the right side, but when revolving on its short axis the appendix may be placed toward the anterior abdominal wall, or it may be placed at the posterior aspect of the intestine. It will be evident that when these motions are concomitant there will be a resultant of motion and that the location of the appendix must vary according to the movement of the cæcum. So far as the mesentery of the appendix is concerned, there is frequently a pouch between it and the ileum consisting of folds of peritoneum; by rotation of the cæcum this mesentery becomes either congested or atrophied and is thrown into a band or perforated, in either way becoming a source of danger to the nearlying intestine, for it may either choke it off as by a cord or ensnare it through the perforation, choking it in true hernial fashion.

If we consider these anatomical relations for a moment, it will be evident first, purely that a physiological motion may result in a dangerous pathological condition, and secondly, that this physiological twisting or revolution approximating it may provoke a symptomatology most misleading, and therefore dangerous so far as it apparently justifies extreme measures. It will also explain how in many cases in which the symptomatology has been presumably grave, the trouble has suddenly subsided and may never again return, for the reason that there has been in reality no real appendicitis by occlusion, retention or secretion, but only a physiological

twist and corresponding irritation which has righted itself. So far for apparent disease of the appendix; now let us look at the real disease, so far as exact location is concerned. It is the universally conceded fact, that in operation for appendicitis, the appendix is not always readily discovered. Some operators fail to discover it at all. Why this should be so, when it is alone the seat of the disease, I do not understand. Why on opening the abdomen it is not always found in the same position is easily explained by the anatomy just referred to. The position must vary with the motion of the intestines with their degree of distension, again by the accidental adhesions of the organ and the adjacent structures, and again by the length of the orgain itself. It has been found in the inguinal canal, now up against the anterior abdominal wall, and again in the floor of the pelvis. In women it is no rare thing to find it mixed up with an ovarian cyst, and it may, by extension of inflammation, cause a perforation of the diaphragm. All the facts being considered, it is fallacy to argue that lesions of the organ must have a mathematical constancy, either of kind or degree, or of situation. There must be variation in all them, according to anatomical peculiarities of the parts, and according to the nature and extent of the adhesions and the duration of the disease. These arguments and facts I consider are sufficient finally to dispose of the real value of the McBurney point, although this has had its justification in the brilliant results of the surgeon whose name it bears, and whose insistance upon the legitmacy and true *rationale* of the operation for the disease under consideration has done so much to give it permanency in the advanced surgery of to-day.

What must be considered operative cases of appendicitis outside the presence of abscess, must perphaps for a long time remain an open question. Pus, the advanced surgeon, no matter where its location, considers a legitimate cause for attack, and when once this condition is present, delay is no longer to be considered. As to the diagnosis of pus, the question of duration of the disease and the accompanying symptomatology of pain and tenderness is always to be considered. The temperature is not necessarily high, is often sub-normal, and if there has been rupture, shock will usually have been present according to the degree of pus-invasion and occupation. If limitation by adhesions has occurred, the patient will rally and further delay will diminish chances of recovery. The point of greatest sensitiveness connot be regular, and is in most instances traceable more to the discomfort produced by the stretching of adhesions, than to the inflammation in the appendix. If the omentum has become adherent at any point, tension, movement of coughing, turning, or any movement whatever, must be more or less painful. In the real presence of pus, if the inflammation is near the anterior plane of the belly, the walls over the seat of the inflammation are apt to be infiltrated and boggy. If, however, the appendix is deep seated in the pelvis, this bogginess, while not discoverable anteriorly, will be discovered by examination per rectum. For this reason, examination by the bowel, which is often left until the last, should be one of the first procedures to establish the diagnosis. If the tumor is above the iliac bone, or near lying to them, percussion may be dull; if, however, the disease is deep seated, there may be tympany, owing to overlying intestine. In arriving at a diagnosis, the moderate and careful use of salines or of calomel is of more than a little use. If the inflammation is only congestive, or is mechanical, the emptying of the loaded bowel will relieve pressure, and thereby permit a general resolution with the abatement of all the symptoms. Moreover, if the tumor is fecal, this is removed and a diagnosis rendered possible if other mass remain. The use of the aspirating needle is precarious in the extreme, and is not to be advised. Pus may be so deep seated as to escape detection, and on the other hand so situated that perforation of the sac containing it be a most dangerous step. Again if the condition of the patient is such as to justify exploration of this nature, incision is no more dangerous and much to be preferred, as at once making a diagnosis, and affording a means for relief. In long-standing cases, motion of the right leg is accompanied by pain, and the thigh is constantly flexed, while its complete extension is either impossible or accompained with great pain. With the mind directed to the operative features of the disease, careful observation along all the

phases of the attack will generally enable a distinction to be made between cases essentially abscess-like from the start and those of a less degree of inflammation. Among the latter that claim the attention of the surgeon are those recurrent in their type. Given a case recurring at various intervals, each recurrence marked by an increase in the seriousness of the symptoms, to the surgeon holding in mind the probabilities of the case, operation will be usually certain of selection. Every patient holding within his abdomen sufficient cause for periodic attacks of this nature, is never free from danger of a last fatal attack. In these instances the operation during the quiescency of the disease is to be considered. To my mind the argument of Senn for operation after a primary attack of appendicitis, granting that the nature of the disease is well established is logical, and the practice in good hands safe.

In the minds of many, the non-surgical treatment of appendicitis has by far the best of the argument. Case after case is cited in which recovery has taken place under the use of opium, and therefore, in the minds of those who pin their faith on the claims of Alonzo Clarke, surgery has little, if any excuse in appendicitis, if it be remembered that pain and tympany, and rise in temperature, may all exist in the right iliac fossa without the existence of appendicitis at all. Hence if a localized peritonitis, produced by the twisting or revolution of the intestines is present, opium will relieve the pain and consequently, as the gut is also thereby put at rest, in the interim it will have regained itself and the symptoms will abate.

The same logic follows the calomel or saline treatment.

If the gut is slightly twisted and congested, if it be freed from its contents and therefore given a greater possibility of physiological contractions, the normal integrity and relations are at once restored and the pain is at once relieved. Even in the presence of pus the relief of the congestion, brought about by the use of salines often conduces to the greatest comfort of the patient and gives a relief that seemingly interdicts operation. The same is true in tubal and ovarian pus disease in women.

It will thus be seen that the two methods of treatment in the non-suppurative forms of inflammation both accomplish the same thing in essentially the same manner.

---

### Intertrigo.

Dr. W. de Garmo (*La Semaine Medicale*, No. 12, 1893) recommends the following powder as superior to all other measures in the intertrigo of children and adults:

℞

| | | |
|---|---|---|
| Powdered starch | | gms. 120 (℥iv). |
| Prepared chalk | | gms. 60 (℥ij). |
| Burnt alum, Powd. boric acid, | āā | gms. 8 (℥ij). |
| Carbolic acid | | gms. 2 (gtts.xxx). |
| Essence of lemon | | gms. 1 (gtts.xv). |

Mix and reduce to an impalpable powder. Use as a dusting powder.

—*Pritchard.*

---

### A Good Alterative.

Dr. Clark of Youngstown, O., furnishes the following formula to the *Medical Summary*:

℞

| | |
|---|---|
| Syr. sarsaparillae comp. | ℥ij. |
| Ext. burdock fld. | ℥j. |
| Ext. taraxaci fld. | ℥j. |
| Syr. acidi hydriodic. | ℥iv. |

M. Sig.—Teaspoonful in water three times a day.

---

### Cramps of the Legs in Pregnant Women.

Administer at bed-time .5 milligrames of sulphate of copper. This can be given every night without inconvenience.—*La Gazette Medicale.*

---

### Otalgia.

The receipt given below has been found useful:

℞

| | | |
|---|---|---|
| Menthol, Camphorae, | āā | gr. xx. |
| Liq. Albolene | | ℥i. |

Drop in ear p. r. n.

---

### Urticaria.

Bordeaux has found the following prescription to give great relief in urticaria:

℞

| | |
|---|---|
| Liquor calcis, Aquae Laurocerasi, Glycerini | equal parts. M. |

Sig.—Apply externally and cover with cotton.

---

THE subject of animal speech, which is now attracting much attention in the scientific world, will be treated by Professor E. P. Evans in the opening article of the August *Popular Science Monthly*. Professor Evans gives much striking evidence to show that animals communicate among themselves by vocal sounds, and that many of them learn the meaning of human speech.

# CURRENT LITERATURE REVIEWED.

THE AMERICAN GYNECOLOGICAL JOURNAL.

for May. Dr. Alexander J. C. Skens contributes a paper on

**The Pathology and Treatment of Injuries of the Pelvic Floor.**

He divides all the injuries of the pelvic floor into two classes: First, those that occur in the median line of the floor and in direction corresponding to the axis of the pelvis; and second, those injuries that occur above the floor itself, transverse internal lacerations. The laceration in the median line occurs in various forms, from a solution of continuity of all the tissues extending from the posterior commissure to the sphincter ani to a complete laceration of the sphincter. To these well recognized injuries he adds another as the result of his observations, viz., subcutaneous laceration of the muscles and fascia in the median line usually limited to the transversus perinæi muscles and fascia, but in rare cases involving the sphincter ani muscle.

The second class of injuries, which are transverse, and have been described as internal lacerations, consists in laceration of the fibres of the levator ani muscles and fascia, and this is usually attended with separation of the muscular layers of the vaginal walls from the pelvic floor. In some cases the laceration is complete, involving the mucous membrane as well as the muscular coat of the vagina, and, in very rare cases, the laceration extends upward and outward as far as the levator ani muscle extends, but as a rule the laceration of the levator ani is subcutaneous, that is to say is not attended with laceration of the mucous membrane of the vaginal wall.

In the median line injuries, extending from the posterior commissure down to and including all the tissues of the pelvic floor at this point, he operates simply by removing the scar tissue, and in so doing vivifies the ends of the muscles and fascia that have been divided. The vaginal wall, which has been attached to the lower angle of the laceration, is liberated and raised up so as to form the inner surface of the pelvic floor. In complete laceration involving the sphincter ani, he follows closely the principles involved in the Emmet operation.

In operating on the transverse or internal lacerations, he follows the classical operation of Emmet so far as the lateral denudation in the vagina and suturing are concerned. In the median line he removes only enough tissue to liberate the vaginal wall from the pelvic floor and then reflects it backward and upwards. He then divides the tissues in the median line down to the sphincter ani muscle, or down to where he finds muscular tissue and fascia, thus producing by incision a complete median laceration. The angles in the vagina are then brought together by sutures down to the muscular tissue of the pelvic floor. The muscles, fascia and integument are then closed by sutures from below upwards; the enlarged vessels and cellular tissues are then crowded backwards towards the rectum and the vaginal wall united by to the pelvic floor with the sutures, which bring together the lateral edges of the floor of the pelvis. In this way the essentia requisites are obtained: first, the central part of the floor is restored, the so-called rectocele is disposed of without loss of the vaginal tissue, the normal relations of the vagina and pelvic floor are established, and the overdistended veins receive more support than can be afforded by any other operation known to the author.

Dr. J. N. Martin discusses the subject of

**The Surgical Treatment of Fibroid Tumors of the Uterus.**

The various operations for the relief of those suffering from these tumors are discussed by the author who sums up his paper as follows: "I approve that method, with conditions favorable, which leaves the cervix with the stump treated intra-peritoneally, and the lower segment of the broad ligament, for the following reasons:

First. It leaves a stronger floor for the pelvis, and it leaves the vagina in a better condition than when the cervix too is removed.

Second. It is better than fixing the stump in the abdominal wound as it permits of free dilatation of the bladder and there is no traction. The recovery is more rapid, as there is no sloughing mass left to separate and interefere with the healing of the abdominal incision. The operation can be completed with a short pedicle.

Third. The vagina is left in a better condition than with Byford's method. By his method the cervix and tissues about it are twisted out of shape and a mass is left to separate.

If the intra-peritoneal method is adopted we should be sure that the hemorrhage is controlled, exercise perfect aseptic methods in the operation and toilet, and to be certain, drain from the posterior cul de sac."

Dr. Mathew D. Mann also furnishes a paper on

**The Operative Treatment of Fibroid Tumors of the Uterus.**

In regard to oophorectomy the author believes that the operation has a field but a limited one. He would confine the operation to those cases where a small fibroid is associated with diseased tubes or ovaries.

His objection to the supravaginal method with the clamp is that the tightening of the clamp gives the patient great pain and that convalescene is prolonged. He urges the necessity of drainage in all cases after the intra-peritoneal method of removing these tumors. He also considers the Trendelenberg position an essential to the proper performance of the operation.

The final paper on

**The Treatment of Uterine Fibroids.**

is from the pen of Dr. Henry T. Byford. The author regards electritity as applicable to interstitial growths, submucous fibroids that do not project much into the uterine cavity. Subserous, multiple and hard tumors, whereever situated, are not much affected by its use. The author states that he employs vaginal fixation almost exclusively in hysterectomy. Abdominal fixation he says is perhaps a trifle the safest, but it is so often followed by hernia, and has such a prolonged and disagreeable after treatment connected with it, that it must be superseded by the first method that will show as good statistics.

Dr. J. M. Baldy contributes a paper on "Carcinoma of the Uterus" in which he urges the necessity of early diagnosis and the early removal of the uterus. Dr. A. Lapthorn Smith discusses "Some of the Elements of Success in Coeliotomy". The author lays stress on the prevention of handling of instruments and ligatures by visitors. He believes stitch hole abscesses are due very frequently to bruising of the structures by pressure forceps or from sloughing from sutures tied too tightly. Of all material for sutures he preferes silkworm gut. He considers the use of the drainage tube in proper cases as a material aid to the success of the operation, as is also irrigation. He advises that the silk worm gut sutures be left in place for a month in order to avoid the possibility of hernia. This, he says, it is perfectly possible to do if the sutures are aseptic and covered with dry boric acid powder.

Dr. Robert T. Morris contributes a paper on

**Appendicitis.**

advocating the operative treatment. In regard to the use of opium in peritonitis he gives the two following definitions of the drug:

"First. A drug which stupefies the physician who gives it more than it does the patient who takes it.

Second. A drug which greatly relieves the distress of the physician who without it would be compelled to do something rational for the patient who has put confidence in him.

Opium and peritonitis breed a vampire which lulls the patient to sweet repose while his life is being sucked out, and the doctor is looking the other way."

Dr. A. F. Kinne relates a case of "Dislocation of Both Knees Forwards during Intra-uterine Life."

The remaining papers are: "Conservatism in Operative Midwifery" by Dr. R. R. Lawrence; and "The Induction of Premature Labor" by Dr. L. Ch. Boisliniere.

---

THE MONTREAL MEDICAL JOURNAL FOR AUGUST.

The principle article in this month's issue is that by Dr. L. D. Buckley on

**The Treatment of Lupus Erythematosus with Phosphorus.**

The author states that he has seen the lesions disappear under the treatment in a very considerable number of cases and in a number of instances he has had the patient under observation for a length of time after the cessation of treatment. He asserts that there has been little or no difficulty in taking the phosphorus when the dose has not been pushed too actively. But the remedy should be given carefully. He believes that we must look for its action through the nervous system.

The form in which he now administers the the phosphorus is in a solution,

℞ Phosphorus.....gr. vj.
Absolute alcohol .. .....5xxx.

To be dissolved with the aid of heat and agitation, and then mixed, while still warm, with the following mixture also warmed:

℞ Glycerin..... 3ixss.
Alcohol..... 3jss.
Essence peppermint..... 3ss.

Each drachm contains $\frac{1}{20}$ grain of phosphorus.

In most cases he begins with fifteen drops, in water, three times daily after meals. It is well to have the water added quickly after the liquid has been dropped out in an empty glass, and the dose should be taken at once, as he believes that the presence of water changes somewhat the taste of the free phosphorus; if exposed to the air the phosphorus oxidizes, and the less efficient phosphoric acid is formed. Commonly the dose may be increased by one or two drops daily until thirty are taken three times daily; the dose is then increased more slowly, one drop every other day, until forty or forty-five are taken each time, and in rare cases, if it agrees, even a larger amount may be given; but seldom has he given as much as sixty drops at a dose. As the disease yields the dosage is still continued, if well borne, even until the lesions have quite disappeared and superficial cicatrization has taken place.

It is well to watch patients very carefully while taking this remedy, noting the condition of the tongue and of the digestion, and with the least disturbance the drops should be stopped for the time, and proper measures instituted to restore the deranged functions. If there is any constipation or signs of liver disturbance he gives a mild dose of blue-mass, colocynth, and ipecac, repeated on the second night after; if then the bowel discharge has been free and the tongue is not coated the drops may be resumed at a smaller dose than when stopped, and the amount again increased, yet more slowly and cautiously.

In many instances the greatest benefit will result from the administration of full doses of nitric acid after each meal, well diluted, in the interval of cessation of the drops, say for a week, when they may be returned to as before. This course of nitric acid may be repeated from time to time with advantage.

When there is much heat and flushing in the eruption, it will often be better to give, in place of the nitric acid, the acetate of potassium, in doses of fifteen grains, with the fluid extract of rumex, and nux vomica, well diluted, half an hour before meals, as in acne rosacea. This he has sometimes seen to have a most beneficial effect upon the eruption, and when the phosphorus has seemed to have lost its effect on the

lesions, he has observed it to take hold of them strongly after a course of a week or so of the acetate and rumex mixture.

Dr. N. D. Gunn contributes a paper on "Gastric Neurasthenia." Washing out the stomach, he states, will often relieve the patient when everything else fails. Change of air is also of use and, in the depressant form of the disease, stimulants and forced feeding are valuable.

Dr. D. J. Evans reports a case of "Dystocia due to Hydrocephalus." The child was born by the breech but it was necessary to reduce the size of the after coming head to allow of delivery.

Dr. C. F. Martin reports a case of "Ligature of the Femoral for Popliteal Aneurism, Subsequent Gangrene of the Leg, Amputation with Satisfactory Result." The remaining paper is the report of "Six Months Medical Evidence in the Coroner's Court of Montreal" by Drs. Wyatt Johnson and George Villeneuve, who were employed as coroners physicians during the period.

# PERISCOPE.

## MEDICINE

### Poulticing the Ear.

Poulticing the ear may seem to be a simple operation, but there is nevertheless a right and wrong way of doing it, and it appears that the wrong way is the one usually adopted. Dr. Buck says that while heat is one of the best remedies in painful inflammations of the middle ear, and the poultice is one of the best methods of applying heat, as usually put on the poultice has little effect. What should be done, he says, is first to fill the external auditory canal with lukewarm water, the head resting on the unaffected side upon the pillow. Then a large flaxseed poultice is applied over the ear as hot as it can be borne. The column of water is thus kept warm and acts as a conductor of heat between the poultice and the inflamed surface.—*N. Y. Med. Times.*

### Miliary Tuberculosis and Gummata occurring in the same Lung; Differential Diagnosis.

Dr. Eugene Hodenpyle (*New York Medical Record*, December 3, 1892), says the differentiation between miliary tuberculosis and small gummata is often exceedingly difficult. The following points of differential diagnosis may be emphasized, although, of course, there are many exceptions to the general statements made:

1. The history of tuberculosis in the one case, and of syphilis in the other, may be of importance.

2. The bacteriological examination is usually positive in tuberculosis, unless the tubercle are very old and fibrous; it is negative in syphilis.

3. Inoculation experiments are usually positive in tubercle, and negative in gummata.

4. Tubercles are usually present in considerable numbers, and are scattered throughout the entire organ and throughout the body; gummatous deposits are usually single, or are present in small numbers, and are confined to a single organ.

5. Tubercles are usually much smaller than gummata.

6. Tubercles show a marked tendency to undergo cheesy degeneration and to form cavities: gummata rarely become cheesy, usually drying up and undergoing calcification.

7. Amyloid degeneration is sometimes present in tubercles, but, so far as known, is absent in gummata. On section, the tubercles appear as round or irregular grayish masses, often soft or cheesy in the centre, and surrounded by a zone of inflammatory products.

8. Microscopical examination will show the presence of tubercle bacilli in the tubercles; but no characteristic micro-organism is present in syphilis. Giant cells are present usually in tubercles, and are usually absent in gummata.

### The Changes in the Cardiac Ganglia in Acute and Subacute Endocarditis.

Kusnezow (*Arch. Path. Anat. u. Phys.*) concludes his lengthy and interesting paper as follows:

1. In acute endocarditis the observed changes in the cardiac ganglia occur in the form of inflammatory granulations, proliferation and swelling of the endothelium of the capsule, and albuminoid and fatty degeneration of the nerve cells.

2. The changes in the ganglia in the lower part of the auricular walls depend, in the main, upon the extent of the process of granulation by continuity of tissue from the valves to the fatty tissue surrounding the ganglion.

3. Vacuolation of the nerve cells was not observed in acute endocarditis.

4. Pigment degeneration of the nerve cells of the heart is not always a physiological appearance, and does not always depend upon the age of the individual.

5. In hypertrophy of the heart, pigment accumulations in the protoplasm of the nerve cells is a common appearance.

6. The alteration of the cardiac muscle, in the majority of cases, stands in no constant relation to the changes in the cardiac ganglia.

7. Only in rare cases is it possible to establish a dependence of the power of the heart upon the diseases of the cardiac ganglia, in a pathologico-anatomical manner, during life. —*Lancet Clinic.*

### Blood Changes in Syphilis.

Neumann and Konried (*Wiener klin. Wochenschrift*) have made a study of the blood in all stages of syphilis with the following results:

1. The hemoglobin is diminished in the primary stage from 15 to 30 per cent. It remains diminished during the first part of the eruption and in early treatment, but as the mercurials are pushed it rapidly regains its normal percentage.

2. Older contracted cases of secondary syphilis have only from 45 to 75 per cent. of hemoglobin. The anti-syphilitic treatment in these cases increases the hemoglobin, but does not raise it to normal.

3. The late forms of tertiary syphilis are characterized by a low hemoglobin percentage, which improves under mercury.

4, 5, 6. The red blood corpuscles are not diminished in the primary affection, but when constitutional symptoms appear they are reduced one-third. Anti-syphilitic treatment brings them back to normal. Non-treated secondary forms have about one-third the normal amount, which becomes normal under treatment. In the tertiary stage there is some diminution. The number becomes restored by treatment.

7. The number of white corpuscles are diminished in proportion to the diminution of the red corpuscles.

### A Variation in Type in General Paralysis.

Bullen's views on this point are (*Jour. of Mental Science*, April, 1893) that although in every particular the type of general paralysis cannot be said to have universally changed, yet it is probable that in some feature or another alteration is to be noted very generally, and that in some localities prominent changes are apparent in the whole form, and that in the following details we may especially look for evidence of variation:

1. Less pure and sthenic type of mania, with more infrequency of occurrence.

2. Greater frequency of primary demented cases, and an earlier onset of dementia in cases where emotional manifestions are primary.

3. Possible increased ratio of melancholic to maniacal symptoms.

4. Modification in the ages of patients attacked, in the duration of the disorder,and in its distribution as to sex.

5. Variation in the relative frequency in occurrence of convulsive and apoplectiform seizures; in a less sthenic character of the former, and in diminished frequency and fatal significance of them.

6. A possible concurrent change in the meningo-encephalic adhesions (post-mortem).

### Tuberculosis Caused by Bites.

A curious and instructive case is recorded in a French contemporary. A women presented herself for treatment at a hospital under the following circumstances:—Six months previously she had been bitten on the index finger of the right hand by an epileptic who was suffering from phthisis. The wound resulting from the bite at first began to heal quickly, but subsequently by degress it commenced to ulcerate, and in the end it became distinctly tuberculous. Three or four months later the physical signs of tuberculosis became apparent in the lungs. Another and similar case is recorded where tuberculous ulceration of the finger resulted from a phthisical husband biting his wife. Auto-inoculation in tuberculous persons also seems possible. Terson of Lille mentions the case of a man who bit his tongue, and the small wound so resulting developed into a tuberculous ulcer, the man being phthisical at the time.—*Med. Press and Circular.*

## SURGERY.

### Treatment of Appendicitis.

Dr. N. Senn concludes an interesting paper on this subject as follows:

1. All cases of catarrhal and ulcerative appendicitis should be treated by laparotomy and excision of the appendix as soon as the lesion can be recognized.

2. Excision of the appendix in cases of simple, uncomplicated appendicitis is one of the easiest and safest of all intra-abdominal operations.

3. Excision of the appendix in cases of appendicitis before perforation has occurred, is both a curative and prophylactic measure.

4. The most constant and reliable symptoms indicating the existence of appendicitis are recurring pains and circumscribed tenderness in the region of the appendix.

5. All operations should be done through a straight incision, parallel to and directly over the cœcum.

6. The stump, after excision of the appendix, should be carefully disinfected, iodoformized, and covered with peritoneum by suturing the serous surface of the cœcum on each side over it with a number of Lembert stitches.

7. The abdominal incision should be closed by two rows of sutures, the first embracing the peritoneum, and the second the remaining structures of the margins of the wound.

8. Drainage in such cases is unnecessary, and should be dispensed with.—*Cal. and Clin. Rec.*

### New Operation for Bad Cleft Palate.

Mr. Arbuthnot Lane operated on a case of cleft palate by means of a method which he had adopted on a previous occasion. The child was two years of age. The upper lip, with the hard and soft palate, was cleft from before backwards, and the cleft in the palate was of such a nature that it was hopeless to attempt to close it by any of the usual methods. On one side the palate terminated by an oblique junction with the lower end of the vomer, whilst on the other side there existed only the alveolus, which above

was directly continuous with the inferior meatus of the nose. Mr. Lane removed the mucous membrane from the margin of the hard palate on the one side, and on the other he stripped the mucous membrane from the inferior turbinated bone and from the inferior meatus, and so formed a goodsized flap of mucous tissue and periosteum whose base was continuous with the mucous membrane lining the inner asept of the alveolus which formed one boundary of the cleft. This flap was then made to cover in the cleft, being connected by a continuous suture with the opposing freshened edge. There was no possibility at the time of bringing the edges of the soft palate together, so this portion of the operation was postponed till the hard palate had developed a little. Nothing could have been more satisfactory than the result which was obtained from this method. Mr. Lane pointed out that it admitted of a tolerably wide application, though he had seen very few cases like the above in which it was so peculiarly applicable, and which were apparently not capable of being treated by the ordinary methods.—*Med. Press and Circular.*

## ARMY AND NAVY.

U. S. ARMY FROM AUGUST 6, 1893, TO AUGUST 12, 1893.

Leave of absence for twenty days, to take effect upon the conclusion of his examination for promotion, is granted first Lieutenant James D. Glennan, Assistant Surgeon, U. S. Army.

First Lieutenant Charles E. B. Flagg, Assistant Surgeon, will proceed to the Yosemite National Park, California, for duty with Troop 1, 4th Cavalry, relieving Capt. Leonard Wood, Assistant Surgeon.

Upon being thus relievied, Capt Wood will return to his station, the Presido of San Francisco, California.

Leave of absence for one month, to take effect, about August 16, 1893, is granted Captain Henry S. T. Harris, Assistant Surgeon, Fort Keogh, Montana.

Leave of absence for one month, to commence about September 5, 1893 is hereby granted to Major J. F. Lauderdale, Surgeon, U. S. Army.

Leave of absence for three months, to take effect on or about September 4, 1893, is granted Major George W. Adair, Surgeon, U. S. Army.

Leave of absence, for one month, and fifteen days, to take effect, when his services can be spared, is granted first Lieutenant Frank R. Keefer, Assistant Surgeon.

By direction of the acting Secretary of War, the extension of leave of absence, on account of sickness, granted Captain Marlborough C. Wyeth, Assistant Surgeon, is still further extended two months on account of sickness.

Captain Marcus E. Taylor, Assistant Surgeon, having been found incapacitated for active service, by an Army Retiring Board, will proceed to his home and report thence by letter to the Adjutant General of the Army.

Leave of absence for one month, is granted first Lieutenant Alfred E. Bradley, Assistant Surgeon, U. S. Army.

Leave of absence for one month, to take effect upon the return from detached service of first Lieutenant Henry C. Fisher, Assistant Surgeon, is granted Captain Eugene L. Swift, Assistant Surgeon.

## NEWS AND MISCELLANY.

### A "Fair" Companion.

If you intend visiting the World's Columbian Exposition it is of the utmost importance that you learn how to see it to the best advantage, so as not to waste time and money.

To go into the Fair grounds without the aid of a person or guide "who knew it all," or with the use of an ordinary guide book would be very much like seeing Chicago through the aid of the City Directory, or landing alone at one of its various depots. You would be utterly lost, and as for relying on other visitors to tell you what you should do or where you should go, please remember that very few will be better acquainted with their surroundings than you, and the hurly-burly will give no one time to attend to other people's wants or wishes.

The book is called A "Fair" Companion, and is intended to obviate the necessity of a person accompanying you, as the Companion has been made a study and contains much better information than you would be likely to receive from a uniformed guide, for the reason that he would show you what *he* thought was of most interest, while this book shows *it all* and leaves it for you to select what pleases your taste. If you have but one day to devote to seeing the Fair, it tells you what can be done in that time and a choice of three plans how to do it; if you have two days, the work is divided into that time—also a six-day plan. The Companion will also be a valuable aid to the fortunate ones who may prolong their stay for weeks or months, as it gives in concise and consecutive form information that will save days of laborious travel around the grounds in the endeavor to become familiar with the location of buildings and exhibits.

By this means you can work systematically, avoiding loss of time in rambling over the grounds in search of something—you hardly know what—and seeing everything at the most opportune time.

This book has a large map of the World's Fair grounds showing all the roadways, pathways, waterways, buildings, gates, etc.

With the aid of A "Fair" Companion you can see everything to the very best advantage.

**Pharmaceutical Products of the Farbenfabriken vorm Friedr Bayer & Co.**

**Phenacetine-Bayer**

ANTIPYRETIC and ANALGESIC; Prompt, safe and effective in Fever, Influenza, Rheumatism, Neuralgia, Pneumonia, Cephalalgia and all forms of pain.

Phenacetine is given in doses of 2½ to 10 grains, 3 or 4 times daily. It does not depress the heart.

Phenacetine is supplied in ounces, also in tablets and pills, alone and with Salophen, Sulfonal, etc.

**Sulfonal-Bayer**

HYPNOTIC and SEDATIVE; Indicated in all the Insomnias including those of insanity and the Neuroses; Causes no nervous or gastric disturbances. Must be given as directed.

The dose of Sulfonal varies from 15 to 45 grains; It should be given an hour or two before bedtime.

Sulfonal is supplied in ounces, tablets and pills; also in tablets in combination with Phenacetine.

*Other Farbenfabriken Products:*

**Salophen, Trional, Aristol, Losophan, Piperazine-Bayer, Europhen.**

### INEBRIETY.*

R. M. WIGGINTON, M. D. Waukesha, Wis.†

It is hardly necessary to state that this subject needs more than a passing notice. The drink problem of this country is of vast proportions. One million of arrests for drunkenness in the United States during the period of one year, with all its resulting misery and expense, is a matter well worthy the attention of the public. There is probably no question to-day before the peoples of all civilized nations, that is receiving so much attention as that of inebriety.

No matter how we look at the subject, whether as a source of great revenue to the state, as a political factor, as a great moral question or as an agent for the ultimate destruction of the physical and psychical organization of man, it is rapidly attracting the best thought of the thinking men and women of the world. States are adopting stringent rules. Norway is already leading the van with its national regulations. Christianity is uttering its most fervent appeals; philanthropists, philosophers and statesmen are racking their brains for a proper remedy; and even princes and potentates of the Eastern world are seriously considering the subject in all its aspects.

A subject so far-reaching and of such vast importance, a subject that has engaged the attention of the civilized world for ages; a problem so hard to solve, a problem so vital to our social fabric, a problem which involves the very life of the nation, a problem which has for its foundation the health, happiness and well-being of the individual, must of necessity deeply interest the medical fraternity of this country. The very nature and make-up of the medical mind, and the physician's duty in regard to preventive medicine and general philanthropy must naturally fit him for this work.

Already many of the best medical men in the nation have come prominently to the front in trying to evolve from their knowledge and experience a remedy for this great evil—an incubus which hangs like a pall over the human race, eclipsing all other evils combined.

In treating a social evil of this magnitude it is first necessary to understand fully its character and causation; and I regret that the time allowed will only admit of the briefest reference, and of the more cardinal points being given.

The physician in treating his patient first tries to get a correct knowledge of his case; in other words he must make a correct diagnosis. So it is with the subject before us; unless we get a clear understanding of the subject and reach correct conclusions, we shall go along groping in the dark, and no further progress will be made toward solving the problem.

Without further comment or argument we will state that it is pretty generally conceded now by the scientific world that

INEBRIETY is a disease. By this statement we do not mean to say that every one who takes a drink, but who can control or stop it, and does so; or that he who may even take too much under peculiarly tempting circumstances, or to drown sorrow and the like, (if he has no morbid desire or for taste for it), should be called *an inebriate.* So the alienist reasons when he says that every apparently suicidal act is not alone positive evidence that the person committing the act was mentally deranged. So we might reason in regard to the taking of chloroform, chloral, opium and the like, as remedies in disease, notwithstanding the bad effects to which they too often lead. It is only where the imbibation of these articles becomes a fixed and uncontrollable habit with the will power weakened or gone, that we recognize disease.

In treating of organized life, every deviation from a normal or healthy standard must be considered in the light of disease. This fact is recognized in the vegetable as well as the animal kingdom. No one is so familiar with this fact as the horticulturist, the agriculturist, or the breeder of fancy stock. So pauperism and the crime habit must be looked upon and treated as disease in the proper acceptation of the term; and until these facts are recognized and the proper remedies applied in accordance with rational and proved science we shall continue to be cursed with these unnecessary and remediable evils. Inebriety, properly so called, is a disease; and as such, is known by the same morbid phenomena, and is governed by the same pathological laws as other diseases are known and governed.

It is a psychosis; a species of insanity. It is a disease of the brain affecting the mind, in which the predominant and characteristic symptom is a weakening of the will-power and the mental faculties, hence a form of dementia. Not only this, but it is a *disease of the entire nervous and physical organization of the man*; no tissue, no cell escapes; all is involved in one common ruin. These facts are pretty generally conceded by the best men in the medical profession in this country and in Europe. As it is a disease we must deal with it as such, even as other diseases are considered, in regard to causation, treatment and prevention.

*Causation*: The causes of inebriety may be indirect or predisposing, and direct or exciting.

Of the indirect or predisposing causes, chiefest of all is that of heredity. We may quibble all we like over the term heredity—that a man is not born insane, or an inebriate, or a genius, or a criminal, and the like—but we *do* know, that birth *does* take place with these tendencies.

By heredity we do not mean to say that the child *will* of *necessity* inherit the *peculiar* disease or diseases of the parents, or that the child will *surely* turn ou at vagabond because the parents belong to the defective classes; for we frequently see children born of diseased parents, parents with marked physical, mental and normal defects, who under proper environment grow up to excellent manhood, who go through life perfect specimens of temperance, sobriety and moral integrity, but we tremble with uncertainty when we learn the history of these cases, for we know for a *certainty* that the offspring is *always* born with these tendencies strongly marked.

Environment often "makes the man or damns the child." This reënforces heredity, and by these two great laws health as well as disease is governed. By these processes nature makes her selections and moulds her atoms into things of physical, mental and moral beauty and utility.

Knowing what we do of heredity and its subtle laws and processes, we must conclude that the fundamental or ultimate principle lies first in the primitive cell which dates from the time of conception. During the process of cell segmentation, proliferation and growth which follows fecundation, this morbific element or principle is capable of transmission from cell to cell all through uterine life, and when child-life begins, the same parental reflex is carried on until the child reaches man's estate, *when he stands forth a complete composite picture of his progenitors.*

Now, when we remember that man in his physical organization is simply an aggregation of cells, and that every manifestation of this wonderful combination, whether it be physical, mental, moral or emotional, is simply a reflex of active cell growth, we can readily conceive how an *unhealthy* cell growth may contribute to disease. As a result we get an unhealthy physical organization, a weak vacillating and un-

steady mind, a loss of will power, the emotions excessive and the morals low. This tendency of parent to reproduce itself, is a law governing all organic life.

Next in importance as predisposing causes may be mentioned sex, nationality, the drink habit, pauperism, ignorance and the crime habit. In regard to sex, for obvious reasons, it is vastly greater in the male than the female.

Nationality no doubt cuts a large figure in the production of inebriety. The drink habit, through the influence of heredity and environment, is beyond doubt, the most prolific of all causes. Pauperism and the crime habit act in the same manner.

Next in the order of causes may be mentioned the neuroses (which more properly come under the head of predisposing causes) such as insanity, epilepsy, chorea, progressive general paralysis, hysteria and the like.

The exciting or direct causes of inebriety are many. To summarize we might say that *environment* was the exciting cause and covered the whole subject; that all the surroundings and conditions of life of the individual together act as a cause. To particularize we might mention: Bad associations, lack of education, occupation, over work, ill health, insufficient food and clothing, excitable temperament, disappointments, financial disasters, loss of dear friends and *unpleasant home surroundings*. This latter condition might be considered as the most prolific of all the exciting causes of inebriety.

It commences in early youth and drives the child from the home hearth, and for want of careful nurture, parental training and Christian influences, the boy seeks his pleasure in forbidden places and is soon on the road to ruin. Thus we see that *heredity* and *environment* are the two great factors in the production of inebriety.

*Treatment*: After what has been said of inebriety and its cause, it will be readily understood that it is a disease, not like the ordinary ailments with which the physician is brought in contact, but rather a complicated complex affair in which the whole organism of the individual has been laboring under pathological conditions, perhaps, for years. Upon close inspection, it will be found that the executive or will power is weak, that the mind is vacillating and unsteady, that the morals are depraved and the emotions are beyond control. By further examination the bodily health will be found considerably below normal. The man is unable to stand fatigue. He is either too fleshy or considerably emaciated. The heart becomes excitable, the kidneys congested and undergoing pathological change, the liver slowly taking on hypertrophy, atrophy and cirrhosis, and the lungs assuming that peculiar form of interstitial hyperæmia so common with chronic alcoholism. His power to do or to command is departed; his ability to grasp a subject and the power of concentration and retention of thoughts is almost nil. He readily sinks into all kinds of vice and immorality; trifles look like mountains. He is easily elated and as easily depressed. His love of family is changed. His health, habits, tastes, inclinations, yea, even his *desires*, have all become morbid and depraved, and you behold the man only a semblance of what he should be. Every tissue of his body has become diseased.

Under these circumstances, may I ask, is it possible that any one remedy or medicine, or any combination of medicines alone can be relied upon as a cure? In other words, can any morbid habit or taste, like the drink habit or the morphine habit, etc., be cured by medicine alone?

Again, is it possible that a habit, in which the entire man presents a complexity of pathological phenomena, can be recovered from in the short space of three or four weeks?

Does not every honest and intelligent physician turn his back indignantly upon such sophistry? To be sure, the patient might be placed upon proper treatment in that short space of time, and if continued under proper surroundings or environment may ultimately recover. Because a man suddenly ceases to get drunk is no sign that he is cured of inebriety, as evidenced by the large number, who, under temptation, so readily return to their former habits of dissipation.

Inebriety is a very complex disease, and presents a variety of morbid phenomena which require for its treatment and cure the proper application of all those rational and approved remedies and appliances which experience has taught us may be relied upon for the restoration of health. Medicine alone will not do it; confine-

ment will not do it; and imprisonment is worse than useless, as statistics abundantly demonstrate.

*As the entire physical, mental, moral and emotional faculties of the individual are diseased, he is a complete wreck. He becomes incompetent as a citizen, and should be cared for and treated as a ward of the state.* The public has a right to demand this: first, for the welfare of the ward; second, as a public protection; and third, as a matter of economy. In regard to the welfare of the inebriate, no one can question the propriety of proper treatment. Unaided, he is unable to rise above his degradation. He has fallen so low and has become so helpless, that he sinks deeper and deeper, day by day, in the wretched temptations and debaucheries thrown around him on every side, that he finally becomes lost to all sense of shame, or obligation to the public as a citizen, or to his family as a provider and protector. He holds his miserable existence by tolerance only. He has forfeited all rights as a citizen and ought to be treated as an incompetent. He already has an unsavory record in the police courts, has often done duty in the House of Correction, and has cost the public many an expensive law suit. Under such circumstances no one can question the right and duty of the state to take charge of this class of defectives. As a public protection, it is also the province of the state to take care of itself. The right-living public have rights that the evil doer must respect, and no community can carry self-respect until this prerogative is recognized and its mandates obeyed. The evil effects, humiliations, inconveniences, losses and injuries, not to mention the vast number of murders and other major crimes that so often follow as a result of the drink habit, are too numerous and exasperating to go unrebuked much longer. In regard to economy, the mind in its wildest conceptions can form only a faint idea of the vast array of figures required to represent the loss in monied value to the public from the drink habit. We need only refer to the nearly one million arrests made in this country during the past year from this cause alone; and this has no reference to the fabulous collateral expense growing out of the same cause. In regard to *treatment,* the cardinal point to be kept constantly in view, and which is paramount to every other consideration, is the welfare of the unfortunate victim; the danger to the public and the matter of economy being considerations of minor importance, and will follow as a natural sequence. What seems to be the great need, is a just and systematic law by which these unfortunates may be judged incompetent and placed in properly constructed institutions, built and governed by the state, and maintained by the state, and in part, possibly, by the inmates when able to pay. This want is recognized by private individuals in the form of the so-called "Keeley Cures," which are springing up all over the land.

These institutions should harmoniously combine the medical, moral, educational, industrial, correctional and custodial qualities. They should be built with due regard to proper classification. The inmates should be committed under the indeterminate sentence, and a clause admitting patients voluntarily should be inserted in the law, but being subject to the same discipline.

Each institution should possess sufficient land, as farming and gardening should be made strong features in the treatment. With proper machinery, a limited amount of manufacturing could be carried on. With the exception of a foreman or two, the institution should be carried on by the inmates, thus making it, as far as possible, self supporting. The institution should be properly officered; and at the head, under the general supervision of the state board of control, should be placed a physician of known intelligence and experience, with assistants under whose immediate charge the entire workings of the establishment should be placed. In regard to specific treatment, (which we have no faith in) the physicians in charge should be well qualified and the treatment left to them. All the moral influences of a first-class institution should he thrown around the inmates.

The industrial and educational features of the establishment should receive marked consideration. In fact, herein lie two of the most pronounced features of the treatment, especially with the younger classes. In regard to correction, I think nothing of a so-called punitive nature should be used, simply the correction that naturally inheres to a well regulated hospital where a strictly humane and dis-

ciplinary regimen is faithfully carried out. The custodial feature of the institution will always be a pronounced one. Herein will gather a large class, without friends or kin, aged and homeless, weakened in body and mind, and beyond any hope of recovery. Like other diseases, not all can be cured, but all can be benefited. And while all may not be cured, these unfortunate creatures can be kept away from all harm to themselves and others, and the public relieved from the burden of arrests, suits at law growing out of personal encounters, crimes of all kinds, murders, divorces, etc., and many other bad conditions of society the direct result of the drink habit.

There will be three classes represented; the upper, the middle, and the lower. The upper class will include all those from the higher walks of life; the educated, the wealthy, those in professional life, higher official life, etc. From this class, coming as it does from a higher social scale, we must expect the largest per cent. of recoveries. However, this does not always follow, for we occasionally observe the most degraded coming from this class. From this higher social scale will "graduate" the so-called "Keeley Cure" cases. As a class, they have better organization; their surroundings are superior; they have more to live for; and they are received back into life, into the arms of friends and comfort, and as a matter of course be much more likely to remain cured than those coming from the more defective classes. The middle class will comprise that large body of workers and toilers, principally in agricultural, industrial and mechanical pursuits, from which we may reasonably expect many recoveries, but not in such a large proportion as from the higher walks of life. They represent, on an average, a somewhat lower grade in the social scale of life, and as a result will yield a less number of recoveries. To this class will naturally fall the principal industrial pursuits of the institution, through which the establishment will be made, at least, partially self-sustaining.

To the third and last class belong all that vast horde who have been born in ignorance, poverty, wretchedness and vice, and comprise what is commonly called the "criminal classes." They have not the *ability* or even the *desire* to rise above the low level to which they were born, and from this class we must expect but few recoveries. Custodial treatment, with the moral influences of a well regulated institution thrown around the unfortunate, will be about all that can be done for this class.

And now what shall we say in regard to prevention. We may state that it is vastly superior to cure. As in other diseases, our first duty is in the line of prevention. The science of prophylaxis, which is rapidly coming to the front in all forms of disease, is no less important in the one under consideration. Here is an evil that surpasses all others combined, and it is preventable. It is a disease whose chiefest cause is hereditary. Every medical, reasonable and legal remedy should be used to prevent its spread and propagation. It is claimed by good authority that sixty per cent. of all drunkards inherit a tendency to the disease. That is, they inherit an unstable nervous and physical organization which predisposes to inebriety. I think the above is a low estimate. In my somewhat extended experience in caring for this unfortunate class of humanity, I have seen but few inebriates who did not inherit some mental, moral or physical obliquity, if careful pains were taken to look up the ancestry. I believe seventy-five per cent. is nearer the figure. Now, if this large per cent. of drunkenness comes from inheritance as a predisposing cause, and if we were sure that this diseased state of society is preventable, and that large numbers can be cured, how essential it is that every responsible and legal effort should be made to suppress the evil. The law of inheritance, as already shown, is a wonderful process. By it, in the one instance, all the virtues and beauties of a perfect parentage are reflected in the child; by the same law, in the other instance, all that is hateful, hideous and damnable may be handed down from the parent to the offspring to the perpetual torment of future generations.

To prevent the propagation and spread of this evil, the state should have a guiding hand. The two chief factors to be considered are isolation and the interdiction of marriage with the defective classes. These two problems are far-reaching in their nature, but not beyond the hope of accomplishment in the near future. As soon as the unfortunate is isolated and his

surrounding changed, improvement begins. He is out of harm's way, and no longer in a position to hand his diseased organism down to other generations. He is provided with a good home and taught industry; he is placed in an atmosphere of morality and taught to respect the rights of others. No sane person can question for a moment the right and duty of the state to care for its own defective classes. In regard to the interdiction of marriage, it will be a more difficult question. It might be a hard matter to determine or to draw the line and say who should be debarred: yet this can be done through the combined action of good men, governed by a just and humane law, which should be national in character. When the national government shall see fit to create a department of health, with a cabinet officer at its head and with proper branches throughout the different states and territories, these public health problems will all fall naturally under this department and can be equitably adjusted as the needs of each seem to require. Already the lax and unstable character of the marriage laws of the different states is being investigated by legislators and others who have the best interest of the nation at heart, and before long we hope to see the United States enjoying a marriage code, uniform and national in character, which will forever put a stop to the present lax and almost indiscriminate mixing of the sexes. Under one grand department of health all the sanitary measures of the country should be placed, including the vexed one of immigration, disinfection and preventive medicine, epidemics, and defective classes of every description, and by just and humane laws, in time, eradicating forever these mental, moral and physical imperfections from the land.

The next (possibly the first) great factor to be considered in regard to the prevention of inebriety, is the presence of alcoholic beverages throughout the length and breadth of our country. To suppress or regulate the manufacture and sale of alcohol is now, and has been, taxing many of the brightest minds in Christendom. A business of such vast proportions as the liquor traffic of this country, cannot be regulated except through the wisest, most deliberate and persistent action of the state. The manufacture and sale of alcohol cannot be stopped but it *should* and can be limited. A business that has been allowed to grow to such vast proportions under the laws of the state, and thereby fostered in its growth, cannot now be suppressed without compensation, and to purchase the plants by taxation, the people would never submit to. But it seems to me by the very nature of their tolerance, the state, by legislative enactment, has full power to limit the *sale*, and the *demand* would regulate its manufacture. South Carolina, I believe, is now entering upon an experiment in this direction, which will be watched with much interest. Norway, it is said, has proved the success of governmental control. At present, in this country, a license sufficiently high to control its sale is by many thought to be the only way out of the difficulty; and even this can only be done where the citizens are educated up to it. Again, when any incorporated industry injures its employes or the public, there is ample means of redress and compensation. With just reason the same rule may be applied in regard to individual or public damage done through the liquor traffic. This is a broad, difficult but interesting subject and time has allowed me only to touch upon the cardinal points. If I draw the attention of the profession a little closer to this subject, the object of this somewhat desultory paper will be accomplished.

# CLINICAL LECTURES.

## COLD ABSCESS OF FOOT; UNDERLYING TUBERCULOSIS OF TARSUS; AMPUTATION OF LEG; TUBERCULAR ARTHRITIS OF KNEE; AMPUTATION OF THIGH.

ROSEWELL PARK, A. M., M. D., Buffalo, N. Y.

This patient comes before us with the history that, a year ago, he sprained his foot, and that, following the injury, a swelling gradually appeared on its upper surface and the function of the member was lost. He has also lost in flesh and strength and has been obliged to abandon his work in a tailor-shop, while, for three or four months, he has gone about only with the aid of crutches. Two days ago, on admission to the hospital, a large fluctuating tumor was found on the dorsum of the foot; he was coughing and raising material which contained tubercle bacilli and the diagnosis was made of incipient phthisis with cold abscess of the foot. On holding the heel with one hand and pressing against the toes with the other, or on twisting the foot on its axis, pain is produced. The tuberculous disease must, therefore, involve the bones as well as the soft parts of the foot, but its extent can be known accurately only by exploration. I purpose, therefore, evacuating the contents of the abscess and exploring the diseased focus. If the bones are in such a condition that there is no probability of future usefulness for the foot, amputation will be performed. The field of operation has already been shaved and enveloped in an antiseptic dressing although amputation has not yet been decided upon. The Esmarch bandage is applied over bichloride towels to facilitate matters if worst comes to worst, and the cold abscess is opened by a longitudinal incision, exposing a jelly-like mass of tuberculous debris which is not, properly speaking, pus. It will not flow, but is scooped out with the sharp spoon. The diseased process has gone so far that it is necessary to make a counter-opening on the outer border of the foot, and the tissues are so œdematous that serum exudates along the path of the knife. You can see the tendons of the extensor longus digitorum and the muscular mass of the extensor brevis. The tuberculous debris extends more into the tarsus and I have scraped out a mass of rotten bone. This is the condition that I expected to find on account of the tenderness and complaint of pain on manipulating the foot, but if I had not made a free incision, I would not have found the tunnel that leads down to the deep-seated focus of disease. The operation is much like following a vein of ore or coal, which is sometimes thin, sometimes thick, but which must be dug out to the end if the mining or the surgery is to be thorough.

Although it is a pity to sacrifice a member on account of a limited focus of disease, experience has taught that amputation is the safer treatment for such trouble. If I try to save the foot, the probability is that the tubercular processes here and in the lung would react upon each other so as to aggravate the phthisis and render amputation unavoidable later. You see I am washing my hands again as carefully as when the operation was begun, for they have been infected in handling the tuberculous material and I do not want to carry any septic element into the fresh wound which I shall make in removing the foot.

The best operation for removing a foot is that which takes a line at least four inches above the ankle. This fact we have arrived at through the experience of patients and instrument makers, that the best artificial feet can be applied to such stumps. With the long amputating knife, I make a circular sweep through the skin and superficial tissues down to the muscle. After allowing this layer to retract, I cut through the muscle and then, with the dry dissector, separate the soft parts and periosteum from the bones. This takes a little more time but is of advantage to the patient in affording a periosted covering for the stump of the bones. The interosseous membrane is now severed, the retractor applied and the bones sawed. You will notice that I bevel off the anteri-

or border of the tibia with the saw and trim away with cutting forceps any little uneven points that are left. The next point in the operation is attention to the blood-vessels and nerves. Both the anterior and posterior tibial nerves, and any smaller ones that may be seen, are separated from the sheathes of the accompanying vessels, pulled down as far as their elasticity will allow, and severed. If this precaution were not taken, they might be included in the cicatrix and cause a painful stump. After ligating the blood-vessels, I insert deep buried sutures of cat-gut in order to unite over the ends of the bones the firm fibrous structures which make a good foundation for a comfortable stump. No irritating or irrigating fluid has been used on the wound except a spray of hydrogen peroxide, the policy being now to keep wounds clean from the beginning rather than to deluge them with antiseptics. The deep sutures relieve all tension on the skin, which is completely closed with catgut, leaving no provision for drainage, as I anticipate no need for it. Iodoform is powdered over the line of sutures, the stump is annointed with sterilized vaseline and dressed with antiseptic gauze and cotton. Over all is applied rubber tissue held in place by a dampened gauze bandage. Considerable pressure is thus applied so that no hemorrhage need be feared when the tourniquet is removed. In twelve or fourteen days, I expect to remove the dressing and find the wound virtually healed. Of course, if fever or any other disturbance should occur, the dressing would be changed sooner. The stump will be kept rather high for the first twenty-four hours. A laxative will be given if necessary to keep the bowels open.

---

This patient presents a condition in most respects similar to that illustrated in the last case. He is thirty years old. Three years ago he was in the hospital with osteitis of the head of the tibia. There are two scars just below the knee, whether from ignipuncture or incision into the abscess I do not remember. At any rate, he recovered from the trouble and enjoyed good health for some time. A few days ago, however, he returned with a very serious and painful affection of the knee. The leg cannot be completely extended, it swerves outward and there is a tender spot over the inner condyle of the femur, externally marked by a redening of the skin. He lies most of the time in bed with his knee on a pillow and his hands grasping the top of the bed, so as to steady himself for his knee "jerks" every little while; i. e., he has frequent muscle spasms. He has had some elevation of temperature, his lips and face show his serious condition, and he has had so much spasm and jerking of muscles that his sleep has been disturbed. There is a severe acute exacerbation of some chronic inflammation about the knee. On account of the tenderness and slight enlargement of the internal condyle of the femur, we may locate the trouble in that place. You will note that the enlargement has pushed the knee outward and increased the angle which the leg makes with the thigh. There is some atrophy of the limb and the subcutaneous veins are quite prominent, indicating obstruction to the return of blood in the deeper veins. Under chloroform the leg relaxes somewhat, but cannot be fully extended. Let us compare the two legs. Atrophy of the muscles above and below, makes the affected knee more conspicuous; there is, however, some actual thickening over the internal condyle. The inflamed area and the distended veins are brought out more plainly by contrast with the healthy side. The patient has suffered so much that he is perfectly willing to have anything done that may be necessary, even to the loss of the limb. What I shall do will be, first, to find the focus of softening in the condyle and remove it with the curette if possible. If I find a more extensive involvement of the structures of the joints, I shall resect, and if there has been so much destruction of tissue that it seems hopeless to try to save the knee, I shall amputate. The last alternative I hope will not be forced upon me, but I shall plan my first exploratory incision so that it can be utilized either for resection or amputation as necessary. It is made obliquely downward and outward from the internal condyle, over the front of the patella. The patella is firmly attached and, as I cut into the soft tissue over it I find it thickened and certainly tubercular. On opening the joint, I find a large focus of softening and acute inflammatory exacerbation of the older lesion in the condyle. The question is no longer between curetting and resection, but between

resection and amputation. The patella, at any rate, must be sacrificed, and I grasp it in lion-jaw forceps and cut it away from the femur to which it is attached by osseous formation. The tubercular tissue extends all the way around the front of the joint to the outer side. If resection is practiced here, it will be necessary to remove an immense amount of tissue, the leg would be shortened three or four inches and would be stiff. Even then, I should not feel confident that all the diseased tissue had been eradicated. I shall let the final test be the appearance of a sawed surface of the condyles after the first step of a resection. The sawed surface looks better than I had feared, but I have exposed a quantity of tubercular debris in the inter-condylar notch, involving the periosteum.

Amputation is manifestly necessary in this case and I shall not perform it in any typical manner but so as to save as much as possible of the thigh. I cut forward to the bone from behind so as to join the previously made anterior incision. The periosteum is scraped upward on the femur and held, along with other tissues, by the retractor before the bone is sawed through. I find after removing the bone that the great sciatic nerve has been severed just at its division. It is pulled down and cut as were the other nerves to prevent its entanglement in the cicatrix of the stump. The vessels are secured and the tissues united in the usual way. If I had known in the beginning that amputation was inevitable, I would not have proceded in this way, but to have set about a typical amputation of the lower part of the thigh would have been to condemn the limb without a trial.

# COMMUNICATIONS.

## THE DIAGNOSIS AND NOMENCLATURE OF FEVERS.*

NELSON G. RICHMOND, M. D., Fredonia, N. Y.

The aim of this paper is not to discuss the general subject of fevers. It is not hoped to throw light on the subject. Its remarks will be mostly confined to the first week of typhoid, and a variety of fever which the general practitioner of this state, at least, finds most commonly in his practice. It will consider the difficulty of the conscientious practitioner in diagnosing this class of fevers at the outset. When once diagnosed it will show how impossible it is to correctly name, taking the various text-books as a guide.

It is a fact that various types of disease are endemic and more or less confined to certain portions of the world. Moreover, it may be very difficult for a text-book to describe accurately the various diseases of each section. It is barely possible that the type of fever which the writer has most to deal with is confined to the Lake Erie region of western New York; or that he has been guiding typhoid fever for the past twelve years to a successful termination and has been stultifying himself by giving it a less dreaded name.

The classification most commonly found in our text-books and fully described is—typhoid and typhus, malarial remittent and intermittent, pernicious malarial, relapsing, yellow fever and the eruptive fevers of childhood. In other works we find a description of bilious remittent, typho-malaria, gastric, mucous, nervous, hysterical and simple continued fever. We shall exclude from our discussion yellow fever, relapsing, typho-malarial, hysterical, the eruptive fevers and malarial fevers, except as the term malaria may have some bearing upon the question under discussion.

A few words in the first place in regard to diagnosis. All observers agree that it is not possible in many instances to diagnose typhoid before the end of the first week. The conscientious physician, who believes in calling things by their true name, would rather test the confidence of his patient and his or her friends by

*Read before the Medical Society of the State of New York.

delay in naming the disease, that appears brilliant by making an early diagnosis and be obliged to change it at the end of a week. He shrinks from getting the dishonest credit of carrying to a successful issue a case of typhoid when it is a variety very much simpler and easier to manage. It is true, I believe, in many instances that the individual interpretation of symptoms often modifies our diagnosis, and to find a case of typhoid with all the typhoid symptoms as described by Louis in 1829 is a rarity. I was once placed in a very embarrassing situation by the hesitancy of a brother practitioner in concurring in a diagnosis of typhoid fever on account of the absence of some of the symptoms we usually find. The case was diagnosed as an ambulatory type of typhoid, not coming under observation until the second week of the disease. The situation soon becoming serious, counsel was called—one of the brightest and most successful practitioners in that section. On account of the presence of constipation and some other irregularities, he would not admit of the correctness of my diagnosis. The embarrassment was soon discovered by the family and the ignorant father who all along had insisted that his son had "canker on the stomach," naturally considered it a point in his favor. In due time an enema was decided upon. It was successful and the young man had not been in bed but a few moments when he uttered a piercing cry from the presence of pain in the right iliac region. I immediately said, "doctor! perforation!" My face evidently indicated alarm. With a ringing laugh at what he terned nonsense, he refused to admit the possibility of such a complication. It took a long time of active work to control the intense suffering. Abdominal distension, tympanites, fecal vomiting, collapse, and death followed in the usual order. And yet never would counsel admit that it was typhoid fever or the complication, a perforation of the bowel.

Many times have I wished that the consultant had not been such a devoted advocate of the typical cases of Louis.

In regard to the diagnosis of typhus, it is only the initial cases of any epidemic which appear puzzling. Being a member of the Charity Hospital staff of New York, I remember well the onset of the epidemic in the winter of 1881. At lunch one day a house physician said he had several cases in his wards which he could not diagnose. One after another joined in describing similar cases they were puzzled over, until it was found there were twelve such cases. Before the day passed it was found we had twelve cases of typhus fever.

Dr. J. Lewis Smith was my visting physician. About the time of the above incident I asked him to see a case I was uncertain about. Walking up to the bedside of the patient he said, "just listen to his lungs, doctor." As I was bending over for the purpose, he spoke quickly, saying, "doctor, don't do it! Send that man to the typhus fever hospital on my authority. We have already sacrificed too many young men in this hospital from that disease." The man died of typhus the next day.

The type of fever I wish more particulary to call your attention to, with the hope that it may elicit discussion, is a type more common than typhoid in my experience in the Chautauqua District of western New York.

By hastily glancing over my memoranda for the last few years, I find forty such cases for illustration; cases which at no time in their progress seemed to admit of the diagnosis of typhoid fever. In several instances, it seeming wise to take extra precautions, counsel was called and concurred in the diagnosis, by excluding typhoid. In the great majority, the course of the fever was such an uninterrupted, uneventful one that conusel was not considered and very little anxiety was felt as regards prognosis. It seemed a very comfortable sickness. Some being, of course, in the recumbent posture would feel like the average woman on the second day after parturition—perfectly able to go to work. They all recovered. They were equally divided between the two sexes. As regards age, seven years was the youngest and sixty-five the oldest. Twenty-two were under thirty years of age, nine between thirty and fifty, and twelve between fifty and sixty-five.

The duration was from seven to forty-two days, the former period being very exceptional, the latter quite common. The greater number, by far, average twenty-one days. It might have been the myopic vision of the observer, but all of the cases seemed to run in cycles of seven.

Their course was seven, fourteen, twenty-one or thirty-five days duration.

The initial symptoms were precisely like typhoid; slow, insidious and progressive. It was impossible to make a diagnosis, excluding typhoid, before ten days. Then it was reached by an absence of the characteristic symptoms of the latter.

Headache was complained of in some instances, but in most of them not a pain was experienced from the beginning to the end of their sickness. A dull, listless expression of the face, hebetude of mind, furred tongue, loss of the sense of taste and constipation were usually found.

The pulse, normal at the beginning, would average between eighty and ninety during the course, rarely going above one hundred, except in the convalescent stage. Then it was a pulse of exhaustion, not a febrile one.

The temperature gradually rises as a rule, although a high temperature in the beginning is more frequently found in this than in typhoid fever. It reaches its height at the end of the first week, maintains it one, two or three weeks, as the case may be, and as gradually subsides. The defervescence occupies a week. It is not quite the characteristic curve of typhoid. It is more like going up a hill running along a plain and going down again. The afternoon temperature, which persists from day to day and week to week, is from 102° to 103½°. The patient is left weak and emaciated and the convalescence may be more or less protracted.

Probably some have said, ere this, why not call such cases a mild form of typhoid? In answer I would say that the absence of rose-colored spots, iliac tenderness and gurgling, diarrhœa, brown dry tongue, delirium and all the symptoms which would indicate serious conditions has not permitted; this absence of the very symptoms which all authorities agree upon as being characteristic of that disease. The above symptoms, one and all, are in the cases we diagnose as typhoid.

It is always our custom, however, to disinfect the stool at the beginning of every continued febrile attack. It gratifies one that this precaution has been observed when what appears to be a simple case in the beginning turns out to be a serious typhoid. It is, too, a very easy matter to continue the disinfection as a precaution, even though typhoid has been excluded.

What, then, shall we call this type of fever? What do the text-books call it? At the bedside, when once the point is reached, that we can safely exclude typhoid, we say something like this—If some not over-scrupulous physician had this it would be called typhoid. Another would call it malarial. Another remittent. Another gastric. Another bilious. Another typho-malarial, and still another simple continued fever. Each one would be naming it as best he could from his own experience and with no text-book to guide him.

Suppose we call it malarial. Flint, Loomis, Bartholow, Reynolds, Pepper and Niemeyer admit of the term malaria only in connection with the malarial fevers of the south. All observers agree now that in malarial remittent, malarial intermittent, and pernicious malarial fevers the parasite of Laverau is found in the blood and that pigment is deposited in every organ. The same objection is found to the name remittent fever, as all the authorities consulted unite in saying that between remittent and irremittent fevers there is a close relationship and that they are interchangable. Some claim there is no distinction whatsoever. Bouilland terms any attempt to distinguish them as a "nosological superfœtation."

Surely neither the term malarial nor remittent, as now interpreted, can be used, as there is no parasite of Laverau in the blood of our patients.

It is a fact that in a practice of over eleven years, the first patient, having a continuous residence here, is yet to be treated for any disease complicated by true malaria; and the first malarial dose of quinine is yet to be given. Why not call it bilious fever? We frequently have, and this seems to be the name most generally recognized. But we feel like apologizing every time the name is uttered. Moreover Flint says, "The term 'bilious' is superfluous and so far as it has any significance tends to perpetuate a pathological error."

The name typo-malarial cannot possibly apply, as the malarial element is certainly wanting—besides, so few admit of the existence of the fever named such by Sur-

geon General Woodward that further consideration is not necessary.

How about gastric fever? Lebert says this is an infectious disease, and found in an epidemic form. This is certainly not true of the fever in question. Olsen considers its existence as by no means certain and that a great majority of all cases occurring in this country are a mild type of typhoid. As Niemeyer describes gastric fever the picture is more nearly portrayed, but he gives a higher range of pulse than is found in this type. Moreover, there is not pain or pressure in the epigastrium and the variety of gastric symptoms that he describes. Another proof that it is not the fever in question is that the ephemeral fever of a day, mucous and catarrhal fevers are all subdivisions of the variety gastric fever.

Hutchinson, in *Pepper's System of Medicine,* gives a simple continued fever of one to twelve days' duration. After debating the question of its existence, he comes to the conclusion that there is such a fever. This cannot be our type as it is too short in duration. He also says that it is marked in the severity of its initial symptoms. The temperature rises four to seven degrees within a few hours. As to two of the causes of this fever, viz., excesses at table and extreme mental or bodily fatigue, there does seem to be a similarity, for in the great majority of cases a bad breath, foul tongue, a stomach which has been asked to digest more than it has been made able, an inactive liver and an overloaded bowel are the conditions found.

In two of the cases given, the symptoms were especially indicative of exhaustion of the nerve centers. One was a lady of fifty who had lost home and property, her husband, her daughter in puerperal convulsions and a son in a railroad accident within a few years, the two latter being close together. She had the continued fever of more than average duration, but her tongue was clean throughout her whole sickness and all of her sickness seemed to be more the result of a shock.

Another one, that of a young man of nineteen, by dissipation in every form had burned his candle very fast. The fever lasted twenty-three days. The tongue was perfectly clean throughout the whole course. Nature, in each case, seemed to take this method of giving their bankrupt nerve centers a chance to recuperate. They seemed to be types of what might be called nervous fevers.

In a discussion on malaria in the New York Academy of Medicine in March, 1891, Dr. Francis Delafield described four types of fever as he found them. One type resembled somewhat the fever under consideration. He says, "Patients who suffer from a continuous fever lasting usually about two weeks, not often less, not often much longer; the febrile movement well marked, 103° to 104° F. when at its height, which was usually in the afternoon; there was usually a great deal of headache, with more or less perspiration. There were cases of this kind which it seemed impossible to distinguish from typhoid—the fever did not seem to be affected by remedies—it ran its course and stopped when it got ready." With the exception of the considerably shorter course the description of the type by Dr. Delafield comes nearer to the one in question than anything we have yet found. It may be the same fever and yet have a shorter duration on account of its different location. I regret that Dr. Delafield gives no name to this form.

I have taken altogether too much of your valuable time in tearing down. I am frank to say I cannot construct. But since by the general practitioner, the term remittent is already so frequently used with this type I will suggest the name, *Northern Remittent Fever.*

## Splenotomy Performed by Monod.*

He (*Bull. et mèm. de la soc. de chir. de Paris*, T. XVIII, p. 668) reports a case of splenic abscess, its causation being somewhat doubtful to him. The chessy masses were found mixed in the fluid contents of the abscess, suggesting tuberculosis. Microscopical as well as bacteriological examination gave negative results regarding tuberculosis; even vaccination of guinea-pigs with the pus failed to produce the expected result, micro-organisms in no case being present. Ecchinococcus was also excluded after careful examination.

## A Vehicle for Iodide of Potash.

Delavan recommends essence of peppermint and milk as an agreeable menstruum for the administration of large doses of iodide of potash.

# SOME FORMS OF INSANITY AND QUASI-INSANITY IN CHILDREN.*

CHARLES K. MILLS, M. D., PHILADELPHIA. †

Mental disease in children is not very common, neither in a few of its types is it very rare. It has received but little discussion from writers on psychiatry and pediatrics, but it is of sufficient practical importance to claim the attention of general practitioners as well as specialists. Cases both of juvenile insanity, and of what I would term quasi-insanity, are confused with other affections and conditions, as with hysteria, with bad temper, with vice, with the delirium of fever, with meningitis or brain tumor, and even with surgical affections.

Mental disease in childhood is, as a rule, limited to a few forms, and a little consideration will show that this might be expected; as for the full development of certain types of insanity it is requisite that the faculties of the mind should themselves be evolved to a certain point. In a strict sense, the existence of mental disease presumes the previous presence of mind; hence some would exclude from insanity proper idiocy and imbecility due to congenital structural defect, although for practical purposes this is not necessary, as mentality is supposed to be the inherent attribute of the race. Paranoia, or primary delusional insanity, will not in its typical forms be observed in children under puberty; but abortive or imperfectly developed paranoia is not an uncommon juvenile affection, and some of its varieties I shall include under quasi-insanities. Some children are pursued and worried with imperative conceptions, insistent ideas, and morbid impulses and propensities; and, after all, as these are but delusions in the making, if they have any systematization in their fabric, and are not merely the ebullitions of mania or melancholia, the child is suffering from a form of incomplete or quasi-paranoia. I thus refer to paranoia at the outset to emphasize the fact that insanity in children is simple in kind in accordance with the simplicity of the mind itself.

I shall not consider idiocy or imbecility except moral imbecility briefly. Kerlin,[1] who has added so much to our knowledge of moral imbecility, has sometimes used the term juvenile insanity in describing moral imbecility; but it is better to speak of both moral imbecility and moral insanity in children, as all forms of mental alienation in childhood may be properly called juvenile insanity.

The varieties of true insanity most commonly observed in children, are (1) melancholia; (2) mania; (3) choreic insanity; (4) hysterical insanity; (5) cataleptic insanity or cataleptoid insanity; (6) epileptic insanity; (7) moral insanity; and (8) certain quasi-insanities—forms of morbid fear and of morbid doubt, perversion and impulse. We have also so-called etiological varieties of insanity in children, as dementia due to inherited syphilis, febrile and post-febrile, reflex and masturbational insanity; but these and other classes founded on causation, may according to inclination or stand-point be regarded as forms of insanity, or as groupings of cases which indicate simply the important causes of some of the clinico-pathological types.

Let me first say a word or two about melancholia. It is always necessary to distinguish between monomanias or paranoias and melancholias; but genuine, uncomplicated melancholia is undoubtedly seen in children. Sometimes hallucinations are present with the mental depression and sometimes not. Melancholia in a child seldom assumes the extreme form which is so frequently observed in the adult; but now and then a true agitated melancholia or melancholic frenzy is observed. Ordinarily a child suffering from melancholia will be blue, sad, anxious, weeping, restless by day and by night, and wanting in the liveliness and changeability of children. The delusions so common in adults, as of self condemnation, of the unpardonable sin, of coming to want, or of fatal organic disease, are often absent; but children who are brought up in a morbidly religious, or in distressing sur-

*Read before Pennsylvania State Medical Society, 1893.

†Professor of Mental Diseases and of Medical Jurisprudence in the University of Pennsylvania; Professor of Diseases of the Mind and Nervous System in the Philadelphia Polyclinic.

1 Kerlin: A Clinical Lecture on Idiocy and Imbecility, *Medical and Surgical Reporter*, May 20 and 27, 1882.

roundings, sometimes exhibit a delusional state of a religious and painful character. The varieties of melancholia most frequently observed in children, are probably the hypochondriacal, and the excited or agitated.

Suicide in children is not commonly due to melancholia, although it is occasionally, and in these cases an inherited taint is often present. Children like adults are now and then driven to melancholia and suicide by want of care and ill treatment.

Mania is, on the whole, the most frequent form of juvenile insanity; but, as a rule, it is less tenacious, less violent and more curable than in the adult. Much has been and much might be written about it, but I shall here limit myself to a few remarks on the somewhat frequent occurrence of true mania in children who are imbecile or partially imbecile, or who suffer from some form of cerebral arrest which gives rise to spastic palsies, a subject of considerable practical interest.

One year ago I first saw a girl of 12 years old, the victim of a form of infantile spastic paralysis affecting the right side, but especially the upper extremity. When seven months old she had one severe spasm, and none afterward. Her mental development was moderate in degree; but not what it should have been for a child of her age, but she had been docile, obedient, and affectionate, and without any moral perversion. I saw her last one week ago. During little more than a year she passed through an attack of acute insanity having four more or less distinct periods or stages, respectively, (1) of depression or sadness; (2) of excitement; (3)of torpor or lethargy; and (4) of gradual convalescence. In the first, she was moody and melancholy and had delusional religious tendencies. She passed in five or six months into a stage of gradually augmenting mania, in which she was highly excitable and emotional, destructive, inclined to stealing and all sorts of michief; she took the most violent dislikes to her nearest relatives and friends. She wished to be always on the go, and was in a state of constant unrest; at times she had screaming spells, and attacks of stubborness which would last for hours or days; she would talk incessantly, and would not sleep until twelve or one o'clock, and then would awake again at four.

After four months of this mania, without special treatment, her parents finding it practically impossible to administer remedies, she passed into a third stage of great lethargy and torpor, which was ushered in by what her mother termed a severe illness of three weeks with fever. The lethargic period lasted for more than three months. She lay in bed all day long, would not talk, slept much of the time, ate when she was fed, but did not ask for or seem to care for food. Gradually she came out of this state, her complete emergence requiring another period of about four months, at the termination of which, one week since, I found her as plump and well as she had been two years before; her general health perfect for her, although her menstruation had not yet come on. As one result of this attack, however, she seems to have marked increase in the spasticity of her affected arm; and in fact she was brought to me the last time chiefly for consultation as to the propriety of operating on the biceps and other tendons of the upper arm for the relief of the increased and annoying tonic spasm. When she was six or seven years old the tendo Achillis of the affected side had been cut with considerable apparent advantage to her in the use of the limb.

This patient, among other defects, had a high degree of hyperopia, one-eighteenth, with deep physiological excavation of both optic nerves, as determined by Dr. C. S. Turnbull, who believed that in ordinary cases, such an amount of far-sightedness would account for many reflex nervous symptoms, but was not sufficient to cause the acute mental attack.

This case is given somewhat in detail, as a lesson in the diagnosis and prognosis in similar cases, of which I have seen several. One, now a man in years, but less than a child in mind, has had several such attacks out of which he has emerged in nearly but perhaps not quite his old condition.

Some understanding of the subject of moral insanity in children is of great importance to the general practitioner, who is almost invariably first consulted by anxious parents about the unfortunate victims of these disorders. It is probably better that a distinction should be made between moral imbecility and moral insanity in children as well as in adults, although commonly this is not done. The

subject of true moral imbecility is the victim of heredity, and his condition is manifested as soon after birth as it is possible to recognize deficiencies in the moral sense through conduct. I have become only too familiar with this class of cases, presenting chiefly moral symptoms, cases which must be recognized as the subjects of disease, and the special care and treatment of which are forced upon us by every scientific and humane consideration. Such children are incorrigible to reproof and training. Punishment has no effect upon them, or only will be heeded to aid their escape from pressing annoyance or discomfort. Much difference of opinion has arisen with regard to the exact nature of such cases. One contention is that a case of pure moral imbecility or moral insanity does not exist, and that close investigation will always show some intellectual disorder. The difference is probably one of terms. Recognizing such words as morality and immorality, as expressing distinct ideas, no reason exists for not speaking of moral departure or moral disease. The doctrines of moral insanity and moral imbecility are, as Tuke claims, in full accord with the rules of evolution and dissolution as laid down by Spencer and Hughlings Jackson. I could, were it worth while, fill this paper with illustrations of moral imbecility similar to four cases which have been reported by Kerlin,[1] the first an illustration of the incipient prostitute, the second the incipient burglar, the third a hereditary religious hypocrite and egotist, and the fourth a confirmed juvenile confidence man.

In moral insanity as distinguished from moral imbecility, the patient has apparently been born in full possession of the so-called moral sense, as well as of the intellect. The perversion of the moral or affective life has been brought about by injury, disease, or vicious habits. Extraordinary perversions of character have been recorded in considerable number as due to acute fevers in children, as after scarlet fever and malarial fever.

The best method of treating moral imbecility must be sometimes met. In most genuine cases, education and philanthrophy, kindness and cruelty, the Sunday School and the reformatory, the asylum and the penitentiary, will equally fail, or perhaps I should not say equally, as in a very few instances, strengthening of the weak and imperfect coordinating centers may be impossible. To the typical cases, to the vast majority of cases that would come under this designation, belongs the term incorrigible. Some of the most practical and most experienced authorities as Hack, Tuke[1] and Kerlin,[2] believe that education in its ordinary meaning should be largely withheld from this class. The former says of them: "The early detection of these cases is not difficult, they should be subject to life-long detention, their existence can be made happy and useful, and they will train into comparative facility and harmlessness if kept under a uniform, temperate and positive restriction. The school-room fosters the ill we would cure; in teaching them to write we give them an illimitable power of mischief, in educating them at all except to do physical work, we are adding to their armament of deception and misdemeanor." As Kerlin puts it, we should refuse them the ordinary routine of education because "we believe that in educating moral imbeciles we are training experts for the later role of so-called moral insanity."

### QUASI-INSANITIES.

In a philosophical sense sanity and insanity are relative terms whether applied to children or adults Certainly not a few may be properly regarded as on the borderland between mental health and disease, and these are perhaps best classed as examples of partial or quasi-insanity, forms of mental disease which in a certain manner and degree have the attributes of insanity. Quasi-insanity better expresses the idea than such terms as, partial or pseudo insanity, or borderland cases, for the prefix "quasi," as used in English, indicates that the thing spoken of resembles or has the attributes of something without being the latter in full sense. Some of the best examples of quasi-insanity are to be seen in those suffering from those affections which are shown by morbid doubts and morbid fears, and have been described under many names as *folie du doute*, introspective insanity; or as phobias in endless train—claustrophobia, agorophobia, pathophobia, pantophobia, etc.

1 Kerlin: *Medical News*, March 19, 1887, p. 326-327.

1 Tuke: Dict. Psychol. Med.
2 Kerlin: Op. cit.

Some knowledge of these phobias, and of what they import might be of value to many of my brethren not neurologists—to gynecologists and surgeons particularly. They are psychoses, which lead sometimes to oöphorectomies and laparotomies, to uncalled for operations and treatments of various sorts on all parts of the body. They are abortive or imperfectly developed mental disorders. Sometimes they are as transient in duration as they are limited in phenomena; but in other instances a few elementary deficiencies or disturbances may persist without much change or increase, through life. Many of these cases, like certain morbid impulses, belong under the general head of paranoia. They have been described not only as morbid fears or phobias, and as morbid doubts or abulias, but also as emotional monomanias, and even as forms of neurasthenia. They are fundamentally dependent upon the domination of the mind by morbid concepts and insistent ideas.

They are sometimes observed among young children, although more common after than before the period of puberty. There most striking illustrations occur in those who have not been subjected to any physical or mental strain sufficient to break down a healthy organization. Persistent fear of the monomanical type occurring in children is rarely due to overwork at school as is frequently supposed. The cause is generally in the child's progenitor or progenitors.

Not infrequently several of the so-called varieties are present at the same time, in the same case, and some cases belong to a class which has been well described as pantophobia, or fear of everything.

As to cases observed in comparatively young children, Hurd[1] reports one from an account written by the patient herself. When about twelve years old, she began to have strange fancies, as fearing that the blood flowing from a cut finger would harm those who came near her. Later, dressing, walking out of doors, eating, were all greatly interfered with through the same morbid ideas. She feared contagious disease because she might communicate it to others. The insistent idea changed from time to time, but seemed to spring always from the emotion of fear. She eventually recovered. Hammond[1] cites from King, of Sedalia, Missouri, an interesting case of pyrophobia in a boy of ten years old. Day and night he was infested with fear of this kind. On one occasion when the morning was cool he succeeded after a contest with his mother in opening the stove door and pouring a bucket of water over the fire. He is said to have been cured by quinine, the bromides, and the use of evaporating applications to the head.

A boy, 11 years old, developed what was practically a pantophobia, although his disorder exhibited itself chiefly as a pathophobia, or fear of disease. He was kept almost constantly in the hands of physicians. Sometimes his morbid ideas revolved around real affections of slight importance; sometimes his fears and suffering were due purely to morbid conceptions and insistent ideas. Now his eyes were the source of morbid dread, and soon his limbs were the seat of rheumatic pain; he narrowly escaped, after solemn consultation, a laparotomy for "typhlitis," a case of strange metastasis as the typhlitis was probably in his head. To a moderate degree he suffered from mysophobia, spending unusual time at his ablutions, teeth-cleaning, dressing, and in the care and treatment of his clothes. Anything in the nature of a symptom or a disease mentioned in his presence was likely to take possession of him. His morbid notions and apprehensions were fed and encouraged by the unceasing attention of members of his family. He was the only son of a widow, and was under the tutelage of a mother, a maiden aunt, and a grandmother, probably the worst board of management for a pathophobic boy that could have been chosen by perverse fate. He was practically cured by taking him from his home surroundings, disregarding his complaints, forcing him to do things on time and after the manner of others, at the same time carefully but not obtrusively looking after the general health.

Another boy, at the age of ten, began to develop the scrupulous and mysophobic type of monomania; in fact he was, as so many of these cases are, an illustration of an admixture of several of the so-called classes of morbid fears. He was constantly worrying about many things that he said

[1]Hurd: Cited by Stearns in Lectures on Mental Diseases, 1893.

[1]Hammond: Treatise on Insanity in its Medical Relations, New York, Appleton & Co., 1883.

and did in his intercourse with others. If left alone, he would spend hours in bathing and washing himself; and often imagined that he had been polluted or would contaminate others. The symptoms were in many respects like those of the lady described by Hammond,[1] and to whose case he first applied the term mysophobia—who could touch nothing without being irresistibly impelled to wash her hands, and who in many other ways was tormented by the fear of contamination. This boy improved greatly under mental discipline, out door exercise and careful tonic medication.

It may be necessary sometimes to separate a form of *juvenile dementia the result of inherited syphilis* from idiocy and imbecility, whether of syphilitic or other origin, which may commonly be done by the fact that the dementia usually comes on after the child is four or five years old, and therefore when the mental condition has been determined not to have been that of idiocy. In rare cases, it happens that a juvenile or infantile dementia occurs when the child is two or three years old, so young that its true mental status has not been fully determined. With this word of caution as to the possibility of inherited syphilis showing itself in a child otherwise healthy in the first year or two of its life, most of the cases of this form of dementia, will be comparatively easy of recognition. A family history of syphilis will often but not always be obtained. Often the upper incisors will be pegged and notched, and cicatrices at the angles of the mouth, and the characteristic physiogonomy be present; the child will have attacks of keratitis, choroiditis, or iritis, or a history of snuffles, or of rash; and sometimes epilepsy will have developed.

*Masturbation Insanity* as occurring both in children and adults has been both over and under-rated, but on the whole, the tendency has been to the former rather than to the latter. Some alienists almost deny that this vice is ever the true cause of insanity; holding that it, like the insanity is due to the neuropathic state of the individual, or that at the most it is merely a concomitant or an aggravating cause. My experience leads me to believe that while, as is known to almost everyone, the vice is extremely common, especially among boys, it only in rare instances is the true cause of mental disease, but that these instances, though rare must be recognized. Of recent writers, Spitzka[2] has laid the most stress upon masturbational insanity. According to this writer, the typical masturbational psychosis occurs between the thirteenth and twentieth year, and therefore at a time which just removes the subject from consideration in an article on diseases of childhood proper. Occasionally, however, the same symptoms and conditions are observed before puberty, although the dementia then is more like a true imbecility. Infantile insane masturbators are more liable to epileptiform attacks than to outbursts of mania.

## TREATMENT OF SCARLET FEVER.*

W. C. HOLLOPETER, M. D., Philadelphia.

It seems like a work of supererogation to read before this society a paper on the treatment of scarlet fever. Yet medical science has grown within the past few years, and is growing with such phenomenal rapidity, that it would seem profitable for us to pause for a moment on some occasion like this, and review briefly what we have gained to combat so formidable a disease.

The general tendency in the treatment of all diseases, is growing more and more decidedly preventative in character. This is especially true of the eruptive and contagious diseases and we are succeeding, in a great measure, in limiting their spread. Within the last decade, while we have yet our annual visitation of measles and scarlet fever, we do not have such widespread devastations as formerly. The large cities always contain a certain proportion of diseases of this character, and it is a source

1 Hammond: Op., cit., p. 425.

2 Spitzka: Cyclopedia of the Diseases of Children, Vol. IV., p. 1047.

* Read before Pennsylvania State Medical Society, 1893.

of frequent wonder that where so many thousand of the unclean are huddled together, we should not have more disastrous epidemics. The solution of this question is found in the fact that more care is exercised on the individual cases—preventative measures are more carefully observed and enacted by the physician and nurse. Not only is this true in house epidemics, but the treatment of the individual cases is more certain in this way of escaping the not the less important sequels.

I have been induced to make these preliminary remarks by observing, retrospectively, with what marked success I have conducted many severe cases of scarlet fever through the most trying and depressing illness. My plan of treatment is very simple. I insist upon rigid, systematic bathing and inunctions, and I continue them even until complete desquamation has taken place. I have by this means had the pleasure of witnessing their complete convalescence without a single sequel.

In glancing over the vast literature of the subject, accumulating and growing more unwieldy every year, I am forced to acknowledge that I have nothing new or strikingly original to announce to you; yet I am startled with the vagueness and uncertainty of the instructions given.

Bathing, in scarlet fever (when it is mentioned at all) is recommended by over a score of our best writers, and our latest text books speak of it as a mode of treatment, yet in such an indefinite and uncertain manner as to preclude any real information, or give the busy practitioner encouragement to resort to it; or, if he should, no positive rule as to method, or the exact technique as to the mode of procedure. In the classical work of Thomas Watson, the prince of observers, and the commencement of modern scientific medicine, now over fifty years old, he coyly hints in the treatment of scarlet fever, "that, if the heat of the surface be very great and distressing he should not recommend the cold effusion, but cold or tepid sponging would be very refreshing and beneficial." This statement seems to hold good at the present day in an uncertain and dreamy way among general practitioners, and is the echo found in every work on practical medicine. The battle-cry of sponging in scarlet fever is universal, yet so vaguely is it touched upon by our best writers, I fear it is not practiced at the bedside by the majority of our medical men.

By actual inquiry I have been satisfied that the majority of our medical men do not give their instructions, as a rule, for the thorough sponging of their scarlet fever cases. They know or feel that they would meet with some objections from the family, or if not open antagonism, the order is partly, if not entirely, omitted. This is due to the old and prevailing theory, found among the laity, that fevers require warmth and sweating, and which has so firm a grasp on the general mind that the doctor usually fears that he will not be able to remove it nor gain his end. I know we have ourselves, as a profession, to blame for the reluctance with which our families accept our methods. When we have discovered the beneficial results from some mode of treatment, we are too prone to overreach our mark, and frequently insist upon an unpleasant method. There is no occasion, except in extreme cases, for ice or wet packs. There is no good to be gained by injurious fussiness.

If we quietly, but firmly, insist upon the patient being most thoroughly sponged, daily or twice daily, with carbolized water, one part to 60, or bichloride of mercury, 1 to 8000, or salt water, or alcohol and water at a temperature of 70 to 100 degrees, according to the amount of fever, and should we remain to witness the process occasionally and thus demonstrate at once its utility, we will speedily convert the patient and his family to our way of seeing the great good to come from the treatment.

This, gentlemen, may seem to you as a more than twice told tale, yet if careful inquiry be made I am quite positive that it will appear that your instructions to bathe have been respected more in the breach than in the observance. Systematic bathing and inunctions protect the body from the more disastrous breakers far ahead of the patient—the numerous sequels that may handicap him for life. I feel that this method of treatment is our most certain prevention of ear, nose and throat trouble, and the thorough annointing I believe to be a prophylactic measure against scarlatinal rheumatism.

My method of conducting a case is briefly as follows: I am in the habit of isolating, in an upper room, all of my cases of scarlet fever the moment a diagnosis has

been made. The room is stripped of all possible hangings and superfluous furniture, and it should be large and well ventilated. No unnecessary visiting should be permitted. The nurse, be it any member of the family, or otherwise, should wear a washable dress and should not mingle with the family unless the clothing be changed or thoroughly disinfected. In the room, if it should be a severe case involving the throat, I keep the gas burning, or a small alcohol lamp, so that steam may constantly be generated. In the boiling water, I frequently add carbolic acid or oil of eucalyptus; this saturates the room very pleasantly, and at the same time, I believe, limits the extent of the contagion.

The patient is now thoroughly sponged with tepid salt water, or any of the antiseptics suggested above, three or four times a day, if the temperature should require it. Immediately following the sponging process, I order the inunctions, which consist of cosmoline, menthol and carbolic acid, ten grains of the latter to one ounce of cosmoline, after the plan of J. Lewis Smith. This combination is exceedingly agreeable to the surface, brings comfort and ease to the patient, and at the same time protects the sensitive surface. Carbolized water, 1 to 40, thoroughly shaken together, may be used to sponge the surface and followed by cocoa butter is also very agreeable.

A point I wish to mention is in regard to the proper disinfection of the physician himself, which, I am sorry to add, is frequently neglected. I find that it is unwise for him to visit other cases, children especially, without protecting himself as well as others. I invariably generate chlorine gas and allow it to go through my clothes thoroughly before I go in other families. This simple process I accomplish in a few minutes by placing a drachm of powdered chlorate of potassium in a saucer, and add a similar quantity of hydrochloric acid; this I place on the floor and stand over the vapor of chlorine as it arises until it penetrates all my clothing, then with the free use of the whisk, and a thorough hand washing I feel that I am clean enough to enter home or any sick room non-contagious.

In regard to the strictly internal medication, I prefer phenacetine for older children, combined with quinine, in capsules. Acetanilide for younger children. I generally give one-half as many grains as there are years in the child's life. When medicine can be exhibited in the form of capsules I always prefer to combine it with quinine to overcome the tendency to depression. Phenacetine and acetanilide act charmingly in controlling the nervous element, relieving headache and fever, promoting diaphoresis, and inducing refreshing sleep. Acetanilide acts much quicker than phenacetine, but its effects are much shorter. I, therefore, choose it for young children, and exhibit it in the form of a powder. If the bowels should be to prid, I combine with the acetanilid, small doses of calomel and soda.

Several years ago, I attempted to carry out Professor J. C. Wilson's chora! treatment in this disease, but was forced to abandon it. The taste was so acrid and lasting, especially on the denuded tongue, and irritable to the stomach, that I was forced to give it up. I fear that we have in this feature alone its most insuperable barrier. The belladonna treatment as a protective or preventative measure, I do not think has any longer a recognition among the profession at large. Those remedies, purely antiseptic, administered internally, have not given promise of their utility as yet. Sulpho-carbolate of zinc and of sodium which, by their breaking up in the system and liberating carbolic acid, cannot be used in a sufficiently large dose to meet with success. The syrup of phenic acid is used by many physicians, but their success as yet does not seem to warrant it being classed as an efficient remedy.

In my estimation, the most thoroughly scientific treatment of scarlet fever, and the simplest to be found, is in the prophylactic measure of thorough isolation, bathing and antiseptic inunctions, with rigid care and attention to the possible appearance of the many sequels. The care of the nose and throat and, eventually, of the ears, will require all the skill of the medical attendant. I have found it absolutely necessary, if I wish to see my case fully recover without any unpleasant after results, to commence at once, in the early history of the case, to give careful and constant attention to the nose and throat, thus preventing much trouble and danger later on.

I instruct the attendant to use a small atomizer filled with warm water containing bicarbonate of soda in solution, about 20 grains to the ounce. If decided inflammation should occur, I use a solution of peroxide of hydrogen, one part to five of cool water or glycerin, and follow it with an oily preparation, such as liquid alboline containing menthol of five per cent solution. Mulford has a most excellent combination called Blandin compound, which is copied after Carl Seiler's Dobell's tablets, and which has the advantage over the aqueous solution in that the antiseptic remedies are in an oily solution, and are more soothing to the inflamed surface.

If the patient cannot tolerate an atomizer, I frequently make the application of the antiseptic oil by means of an aluminum applicator direct to the posterior nasal spaces. A thoroughly faithful attention to the removal of the secretion of the nose and throat, will prevent accumulation, and hence prevent regurgitation up the eustachian tube, with all its associated ear troubles. In this way I am sure diphtheria can be prevented from gaining its first lodgment; and, if it gains any at all, little trouble is experienced with this dreaded disease. We must keep the already inflamed surface thoroughly aseptic. If, however, pain in the ear should indicate the extension of the trouble up the eustachian tube, we must redouble our efforts. Trouble may take place, not from our failure to remove effete material from the nose and throat, and this, by rendering the inflammatory exudate as little as possible, but the desquamation within the eustachian tube itself may be quite beyond the reach of our detergent wash.

The external auditory canal may become blocked by desquamating epithelium, and this must be removed by gently sponging it out. The crude method of dropping laudanum and sweet oil in the ears is to be condemned, as it serves as a nidus for the collection of dust and dirt, independent of the rapid accumulation of dead epidermis. Since I have given careful attention to the management of nose, throat and ears, as explained above, I have had little diphtheria complicating my scarlet fever, and rarely otitis to confront me later on, as unpleasant sequels.

Scarlatinal rheumatism, I have encountered in but a small proportion of my cases, and then it was of a transient character, leaving no damaged heart valves behind. I am inclined to contribute this fortunate result to the faithful use of daily bathing and inunctions, long continued, or at least until after completion of desquamation. I think this is especially born out by comparing the cases occurring in my private practice within the last five years with those prior to that time, or those less fortunately situated, or those, especially, occurring under my observation in dispensary work.

The last, and most constantly occurring in scarlet fever, is the sequel, known as nephritis. Acute desquamative nephritis is regarded by most writers as a necessary entity, the catarrhal inflammation of the uriniferous tubules bears to scarlet fever the same relation as the bronchial inflammation occurring in measles, and known as acute bronchitis. It is true that the specific poison of scarlet fever is peculiarly obnoxious to the kidneys. It is largely eliminated through them,and here hinges the scientific part of the treatment of this disease; the more active we keep the skin, the less danger is likely to occur to the kidney. If the urine is examined throughout the whole course of the disease we will find in the early stage, that it grows less and becomes more laden with the waste of the body, at times nearly suppressed by mechanical blocking of the uriniferous tubules.

If now the skin is not invited to act to its fullest extent, we will soon find our patient reduced to a comatose state. Free bathing has the happy effect of vicariously eliminating and removes the undue pressure placed upon them. It is unscientific treatment to exhibit digitalis in any form during this stage without taking into consideration the pathological condition. It is like forcing a large cork into a bottle too small for it. Unload the effete material through the skin or bowels and you relieve the damaged kidney. The infusion of digitalis is happily indicated later or when the kidney commences to act.

From what has been thus briefly outlined, I may conclude that in the treatment of scarlet fever:

1st. While we possess no specific treatment for scarlet fever, I am hopeful that we will soon obtain one in the light of our present knowledge; and until we do so,

systematic bathing and inunctions will be found to rescue the largest percentage.

2d. Careful antiseptic treatment of the throat and nose during the whole course of the diseased will reduce the possibilities of diphtheria to the lowest, and render otitis less frequent.

3d. Scarlatinal nephritis may be escaped by the treatment suggested above, combined with a milk or at least a fluid diet.

Finally, it is constantly observed that the unpleasant sequels are cropping out long after the physician has ceased visiting the case. We are indebted to our own indifference for many serious kidney troubles, should they arise, if we do not control our cases for a long time after all acute symptoms have subsided.

# SOCIETY REPORTS.

## THE LOUISVILLE MEDICO-CHIRURGICAL SOCIETY.

*Stated Meeting, July 7th, 1893.*

The President, Dr. T. L. McDermott, in the Chair.

Dr. Wm. Bailey presented an essay on

### BLOOD PRESSURE.

(See page 277 of Reporter, August 19th.)

### DISCUSSION.

Dr. D. T. Smith: It seems to me by reducing this matter to the underlying principles and following them, we can find an explanation of a great many points that would require a considerable time to elucidate.

The prime thing is the *cell*—the heart is a machine that is worked by the cells of the body through the nervous system, the nervous system acting mainly as the medium. What is it that impels the heart to send the blood through the veins? It is the requirement of the cells! There are few cases in which over action of the heart is not due to this. The exceptions are cases of tachycardia which, in a way not yet fully understood, is an abrogation of the nerve control of the heart inducing over-action. These cases are not very frequent, and I do not know the result of study as to the effect in the production of hypertrophy. In almost all other cases, over-action of the heart is caused by cells calling for an increased supply of blood. Whatever blood is needed is sent to a cell by the heart through the operation of the reflex apparatus, the cells calling upon the nervous system and the nervous system in turn compelling the heart to exert itself. The channel of the blood becomes more and more sensitive from the time it leaves the veins until it passes again into the capillaries; the right auricle is less sensitive than the right ventricle, the left ventricle less sensitive than the left auricle, the intima of the small arteries and arterioles being the most sensitive of all. The blood meets with increasing sensibility of channel wall until it reaches the arterioles which in some curious way, are commissioned to control the supply of blood to the cell. If the blood is normal and pure, the arterioles present slight tension, the blood flows quietly on and we have an even circulation. But the blood may be defective, may be poisoned from some cause. In that case the cells are displeased with it; the arterioles, acting upon this suggestion, close against it, while at the same time the cells are calling lustily for blood, The brain answers by compelling the heart to overwork itself to send the blood, and this is the foundation of nearly every case of hypertrophy. Hypertrophy is the natural result.

There may be another exceptional cause of over-work, as is in the case of an athlete, where the contraction of the muscles on the veins accelerates the circulation, but even here it is mainly because over-worked cells require an excess of blood that the heart is over-worked in supplying them. Again the blood may be too thin, as in cases of anemia, and the heart is overworked because the cells demand that deficiency in quality be met by increase in quantity.

As a rule it is not the heart that carries healthy blood, but the one that carries defective blood that works more than it

should, notwithstanding that on all physiological grounds the heart ought to work less on bad blood. It would seem that in anemia, Bright's disease and pregnancy the heart ought to decrease in size instead of increase. But whenever the system is insufficiently nourished, it compels the heart to do more work and the question is just how far we ought to keep that up, how far we ought by therapeutic measures to goad the heart to increased action, when by so doing we are assisting to produce hypertrophy.

It is true that excessive action of the heart means, as a rule, increased blood tension. But we know that over-action of the heart does not always mean increased blood tension. The force may be wasted before the pressure reaches the arteries and arterioles. We may have an exceedingly hypertrophied heart and still have a soft pulse—still have defective blood tension.

So long as the system and the tissues call for blood, they need it and must have it or there is a lack of proper nutrition, and the natural conclusion is that no man with a hypertrophied heart is in good health. No man is in perfect health where the supply is not ample, or where the system is calling for more. The horse is not spurred when the rider is pleased with his gait. To prove that nutrition is never complete a man who has hypertrophy of the heart to an appreciable extent will always give out quicker than one who has no heart trouble—other things being equal.

As to the particular method of medication we should use in these cases, it seems to me if digitalis is to be given it should be in small doses continued for some time. I think better results can be obtained in this way than with large doses for a shorter time. Some writer on this subject claims that better effects can be produced with large doses of digitalis but I do not believe this is borne out by facts, at least it has not been so in my experience. However, I would be slow to give digitalis at all until nature should give up the task of effecting compensation.

A word as to relative tension: When tension exists under ordinary conditions we have usually, an over-strength of the heart, but certain conditions may have the internal tension increased with a weak or weakling heart due to contraction of the peripheral capillaries.

As to the result of tension upon the respiration: It is well known that a failing respiration is revived by blood pressure. All of us have watched, often with very painful interest, at a death where circulation at the wrist is imperceptible, extremities cold, where there is no sign of circulation except the slight beating of the heart, and wondered why the first rapid pace toward death is not continued. Something like it is also seen in cases of shock. A person receives an injury, or there is some marked impairment of vitality which renders the heart incapable of keeping up the circulation of blood to the entire system. As a result nature closes the external capillaries, which forces the blood back upon the brain and heart. The tissues of the extremities can very easily do without blood for a long time; the brain and heart cannot. The brain needs the pressure of the blood. The blood is prevented from circulating in the extremities in order that a relatively increased tension may affect the brain and keep up respiration. We can often assist in bringing on conditions of this kind by turning the patient and lowering the head; sometimes even by reversing the position of the patient, arresting the circulation in the extremities and forcing the circulation into the brain, which produces a condition similar to shock. Shock, indeed, may be regarded as the diminutive of death.

Dr. F. C. Wilson: I think too little attention is paid to the pulse since the introduction of the thermometer. The pulse and the tongue the older physicians used to watch constantly, perphaps selecting their medicines guided by the conditions they found there. I believe these are now often neglected. We simply put the theremometer under the arm and judge by the temperature, perhaps never feeling the pulse at all. Of course the pulse indicates, to a certain extent at least, the actual blood pressure. If we could apply different instruments for measuring blood pressure, it would be more satisfactory, but the practical physician has not time to do this and it can be done only in the laboratory of physiological science. Pressure is not influnced by the force with which the heart propels the blood current alone. Sometimes some of the influence of the force of the heart's action is lost thorough the insufficiency of the

several valves of the heart. If a valve curtain fails to fit properly, part of the force of the current is expended in a regurgitant flow and thus lessens the pressure upon the onward current in the arterial system. When conditions of this kind exist they must be taken into consideration in the selection of remedies, and one may sometimes find it necessary to increase the dose in order to accomplish the desired end. The character of the capillary circulation must always be considered, as much harm might be done by goading the heart to increased action when over-distended because of obstruction in the capillary system, or because of regurgitation that may have occurred incident to insufficiency of the valves. If the chambers of the heart become over-filled and we attempt to cause contraction, it may sometimes bring about a fatal result. I think I have seen instances where sudden death occured from large doses of digitalis under such circumstances. The administration under such conditions of the nitrites and atropia, causing the dilation of the arterioles and capillary system through the sympathetic nervous system would be more rational and we could relieve the over-distended heart in this way. The passage of the blood current through the capillaries depends very much upon the condition of the blood itself and the relations between the blood and the tissues themselves. In the tissues that need blood, if the blood that is brought to them is good, an active interchange of material takes place and the blood current is hastened. On the other hand, if abnormal relations exist between the tissues themselves and the blood, there may be narrowing instead of dilatation, and obstruction produced. Instead of mechanical obstruction as occurs in obstruction of the arterioles, there is a species of obstruction for want of proper mechanical relation between the tissues and the blood current itself, which produces a delay in the circulation. Remedies that act directly upon the heart or directly upon the capillaries, would not relieve such a condition. It depends upon the blood itself.

Dr. J. A. Larrabee: There is a tension necessary in every atom of the body; with the preservation of tension in these atoms we have life, and separation of these atoms is indicative of dissolution. In fact, the relaxation which occurs is simply the giving up of the tension of the atoms; so that when life exists there is a normal tension of these particles, particle to particle, and in this we have an explanation of cell action. The matter of blood tension is important as regards the absorption of medicines. I think it would be well if we would give this matter its full bearing by saying that when we have a normal blood tension we may expect the absorption of medicines. The idea should be to administer drugs which will control the osmosis without which we cannot have a proper absorption of medicines in the system. The nerve supply to the heart, coming as it does from two sources, gives us two sources of failure. Since I have studied this question more closely I have found a great many cases where such disturbances have been on the other side, i. e. through the pneumogastric; cases where this failure was plainly accidental. We have here a change in the tension by the check nerve, an over filling of the ventricles, and where this is taken off we have excitation without the proper proportion of blood. In atheromata we have a lessened arterial tension and see what a wonderful change takes place in the heart muscle, how it becomes degenerated—pari passu with the changes in the arterial coats. This is a life saving change and I cannot think that we want increased tension in such a case. With increased arterial tension we get increased cardiac nutrition, hency the wonderful action of digitalis which should be limited to actual patulency, or lesion of the valves of the heart, and then only given up to the point of compensation. Fatty degeneration of the heart is a condition of reverse compensation and must be looked upon as conducive to the prolongation of life of the individual by protecting him from apoplexy.

In cases of Bright's disease I think we have the best example of what we mean by arterial tension increased by materies morbi circulating in the blood. There we have a plain exhibition of the contracted condition of the arterioles down to such a point that the heart in its endeavor to relieve becomes hypertrophied. The illustration goes further than in Bright's disease. There are many similar conditions; we have a stage in the course of fevers, and I speak especially with reference to the great fever, typhoid, where we have a condition of paleness of the skin with high temperature. Now, I think that

very many of our appliances and very much of our therapeutics are in fault by these cases. There is a condition in the course of fevers in which the dilatation by paresis of the check nerve, pneumogastric, gives the relief that we desire. Here there is a call for nitroglycerine or atropina. I have seen such remarkable results from the administration of belladonna by the mouth to relieve the tension, but far better results may be obtained by a distinct dose of atropina hypodermatically when there is this condition of shock, which it really is; the paleness of the skin being relieved not by forcing the heart to overcome that resistance, but to aspirate the heart by dilating the vessels. I do not fear high temperature with redness of the skin as I do high temperature with paleness, and I believe this is the key-note to hydrotherapy.

In regard to agencies for restoring nerve action when it is diminished either central in the heart or central in the brain. We have means of stimulating the vessels, and only recently since the last paper was read I have had an illustration of carrying strychnia to the extent of $\frac{1}{12}$ of a grain, which was carried gradually to that point and not until I reached $\frac{1}{12}$ of a grain did I get the result desired. I believe that strychnia is one of the greatest agents known for threatened cardiac paralysis in fever, and I think it should be classed under the head of cardiac stimulants. This whole subject of arterial tension is one of which the general practitioner cannot know too much, and I can only regret that I have passed so many years of practice in the early part of my life without paying any attention whatever to it, and I believe others are of the same opinion. It is now with me as I believe it is with Dr. Bailey, and others who have spoken, in all the cases I pay particular attention to the pulse and arterial tension, and regulate my therapeutics upon this basis. Not by temperature alone but by pulse ratio compared with temperature.

Dr. J. B. Marvin: It is very hard sometimes to separate arterial tension from conditions of the heart. It seems to me there are two points that should be borne in mind at the outset. First, that causes outside of the heart may as well as hypertrophy give rise to increased tension, or causes intra-cardial may give rise to hypertrophy, but there is always defective action, then gradual dilatation and lowered tension. It is a curious fact, that Bright's disease is almost always associated with hypertrophy of the heart and increased arterial tension.

All troubles that have a poison circulating in the blood may cause increased arterial tension at the time, and cause an over-action of the heart. If one narrows the point down to the fact that nobody having slight hypertrophy of the heart is healthy, I do not believe you will find many healthy people. There is certainly a difference in individuals in regard to arterial tension. In children there is a marked increase of arterial tension, but you cannot make out any hypertrophy.

In regard to digitalis, I think I give less of this drug every year I practice medicine. I am satisfied that there are a great many conditions of the heart where digitalis is contra-indicated. In certain other conditions I believe it is our best so-called cardiac remedy. In Bright's disease I doubt very much digitalis is beneficial. It is fashionable to give the infusion—I think we have better agents. Certainly by the administration of digitalis in interstitial nephritis, we are goading the heart to increased action which has its effect upon the kidney, and we have already an excessive flow of urine. Why should we want to increase that? I believe a better result may be obtained in renal troubles by administration of the nitrites. In pneumonia I do not give digitalis at all and have not for a number of years. I give nitro-glycerine very frequently and I have prescribed it in $\frac{1}{100}$th grain doses every twenty minutes.

In typhoid fever and pneumonia I rely less upon the thermometer and more upon the pulse. I think we should keep a close watch on the pulse, should feel it frequently at the heart rather than at the waist, as we may be misled. If the pulse keeps below 100 or 120 to the minute, in a person of middle age in typhoid fever, I do not care what the temperature is. The pulse in pneumonia that alarms me most is the one that gets quicker every day.

Dr. Wm. Bailey: I have very little to say in closing. I did not of course enter into an elaborate discussion of this question, hoping to bring out some such discussion as we have heard. I did not refer to disturbance of tension as coming from diseased valves of the heart, where regurgitation is permitted. We all know the benefit of digitalis particularly in mitral

insufficiency; nor did I refer particularly to such diseases as so-called Bright's disease in which the tension is very greatly increased. For a long while I have been of the opinion as expressed by Dr. Martin, that this form of so-called Bright's disease was not difficulty in circulation limited to the kidney but that the changes in the kidney, the growth of fibrous tissue, was at the expense of other organs as well; that the trouble was a universal one. Certainly it is this form in which we of necessity have hypertrophy.

The point I wanted to ask particular attention to was that it was sometimes more rational to modify the condition or size of the vessels than it was to endeavor to accomplish the work through the heart handicapped in this way. I presume the word "Handicap" is understood by all Kentuckians—the best horse is made to carry the most weight in order to give the "scrubs" a chance of winning the race. In other words in my opinion it is better to dilate the blood vessels by proper medicines than to endeavor by increasing the power of the heart to force it to carry the blood through the contracted capillaries. This was the point I wished to make in the paper by asking you to consider the physiological action of digitalis and the nitrites. I believe a proper administration of the classes of drugs represented by the two mentioned—digitalis and nitroglycerine—will bring as good results as any medicine that I know of. I am fully satisfied that often times we could do very much more good by opening or dilating the capillaries, thus increasing the size of the vessels through which exit is made, rather than by stimulating the heart to increased power. We see this most markedly, I think, in such diseases as angina pectoris, where the tension is very greatly increased and the relief of nitrate of amyl is universal. The good effects are noticeable by the first inhalation of nitrate of amyl in the phenomena we call angina pectoris.

I am not inclined to express myself as fully and freely as others have done in regard to the use of digitalis. We cannot solve the problem in a single discussion, and we should carefully study the heart's action, administering remedies which will best assist it in performing its duty. In writing my paper I did not enter into minute details in regard to the proper amount of blood that each portion of the body should receive, nor follow the matter still further and see it was received. I think every day we should be more and more inclined to study the natural causes of disease in getting a clear indication for treatment; taking all these questions into consideration I believe we will make more satisfactory progress. I think that the outlook for the general practitioner is bright, notwithstanding we have not kept pace perhaps with the surgeon in many years.

Dr. D. T. Smith: Why do you think that nitrate of amyl acts by relieving the general tension when, by dilating the arterioles and capillaries, you allow the blood to get back into the capillaries of the heart muscle itself, reviving its strength and removing the pain probably due to the privation of blood.

Dr. Wm. Bailey: It may be from widely extended influences. In conditions of this kind one of the most prominent difficulties we have to deal with is the contraction of the blood vessels. The tissues are requiring more blood, a great amount is being forced upon the arteries and arterioles by the heart, yet the tissues are unable to get it owing to the contraction of the vessels, and the most rational treatment would seem to me to be to dilate these channels, allowing the parts to obtain blood in the natural way.

There is no question but the medicines used in controlling blood tension act largely through the influence of the nervous system. In the first place, digitalis stimulates the heart to increased power; it increases inhibition of the pneumogastric, but, unfortunately, in some cases it likewise contracts the capillaries; whereas, nitroglycerine and the other nitrites, increase the heart's power without contracting the capillaries, thus relieving the pressure. Where you have heart pressure under such circumstances, nitroglycerine is much better suited to the purpose of assisting the circulation than is digitalis; but where digitalis is indicated in some forms of Bright's disease, where there is difficulty in elimination of urine from the kidneys, it is the remedy of all. Under such conditions I think the infusion of digitalis and acetate of potassium will produce relief quicker than any other means. But to say that we should give digitalis for everything where the heart is involved, I think would be very bad practice.

PHILADELPHIA.

**TERMS**:—Five Dollars a year, strictly in advance, unless otherwise specifically agreed upon. Sent three months on trial for $1.00.

**REMITTANCES** should be made payable only to the Publisher, and when in sums of Five Dollars or less, should be made by Postal Note, Money Order or Registered Letter.

**NOTICE TO CONTRIBUTORS**:—We are always glad to receive articles of value to the profession, and when used they will be paid for, or reprints supplied, as the author may elect. Where reprints are desired, writers are requested to make a note of that fact on the first page of the MS. It is well for contributors to enclose stamps for postage, that the articles may be returned if not found available.

SATURDAY, AUGUST 26TH, 1893.

## EDITORIAL.

### INEBRIETY AND ITS TREATMENT.

We invite attention to the article on *Inebriety*, by Dr. Wigginton, of Wisconsin. The magnitude and far-reaching consequences of this great evil are therein clearly apprehended, and the difficulty of its successful treatment realized.

We have recently seen elsewhere a distinction which wou'd help the diagnosis and treatment of inebriety. That distinction draws a broad line between the *drink habit* and the *drink traffic*. Inebriety, as a disease, is of the former, and not of the latter unless it be of the body politic. The treatment of inebriety, as a disease of the *individual*, is for the medical profession. The treatment of the drink traffic as a disease of the State is for statesmanship. Both are proper subjects for study and discussion, and the education of public sentiment, and should be conducted on right lines. If, as Dr. Wigginton has so clearly and properly pointed out, "prevention is vastly superior to cure," and "our first duty is in the line of prevention," and "the presence of alcoholic beverages throughout the length and breadth of our country" is one of the most potent, exciting, or direct causes of inebriety, under the law of environment, is it logical,—is it scientific to suggest that "a license sufficiently high to control its sale is the only way out of the difficulty?" Does experience anywhere suggest just how high license needs to be to control its sale sufficiently to prevent this exciting cause of inebriety? License has been tried all the way from fifty to five thousand dollars and inebriety and its existing cause have continued without abatement all along the line.

Does medical science suggest parallel remedies for other diseases? Are our health authorities now treating the threatened invasion of Cholera and Yellow Fever on this plan? Everywhere the most energetic measures within reach are employed to stamp out their first appearance. If it be wise for statesmanship, in dealing with the liquor traffic as a disease of the body politic, or as the chief exciting cause of disease among its citizens, to continue and protect by law the "presence of alcoholic beverages throughout the length and breadth of our country," why not

recognize and protect the presence of the exciting causes of other diseases? If "the right living public have rights that the evil-doers must respect" and "to prevent the propagation and spread of this evil the State should have a guiding hand," then why should not the State employ its power in stamping out this disease as well as others? Why should the State license and "regulate" the exciting cause, and then establish and maintain hospitals and asylums for the treatment of the disease? True, inebriety is a disease, but the *manufacture* of, and *traffic* in intoxicating beverages that produce it, *is not a disease.* Inebriety is a form of insanity, but liquor makers and vendors are not insane. The two classes,—the disease-producer and the diseased,—are as widely separated as are the physician and his patients,—the disease healer and the diseased.

These and other queries will seem to the physician, who, accepting inebriety as a disease, knows the hopelessness of its treatment while its cause persists in vigorous existance, to demand more rational and scientific treatment.

Let the medical profession and our statesmen and all good citizens study this subject in the light of reason and common sense, and let the several sections of our country in which the various remedies have been tried, be carefully studied as to the persistence of the exciting cause under diverse treatment, and let the lessons be applied, and we may come to that condition of public health which will give relief alike from cholera, yellow fever, diphtheria, *inebriety* and all destructive diseases.

Since the Government has had such gratifying success in preventing thus far the invasion of cholera and yellow fever by the improved methods which medical science has suggested, why should not Congress at once yield to the reasonable demand which has been urged for almost a quarter of a century and appoint a Commission to inquire into the causes and cure of inebriety? No thoughtful citizen can read Dr. Wigginton's article and fail to see that this is a most important and promising field for such inquiry; and yet while one branch of Congress has repeatedly passed the measure the other has as often defeated it. Why? It surely is not because the subject is not of sufficient importance. Neither is it because the public health and morals are not involved; nor because it does not concern the material prosperity of the country. As a mere question of finance it is of far greater magnitude than the government purchase of silver bullion, or any possible change in the tarriff. Do any dissent? Then why not create the Commission of inquiry? It is not because the information is not accessible. It is, in every possible relation to the subject. Inebriety is an old disease, and yet but recently recognized as a disease, and even yet there are many who do not so regard it. All sorts of remedies have been tried by scientific, and quack statesmanship, and the most conflicting reports of results fill the air. Why not have a Commission of able, scientific gentlemen who will search out and set in order the real facts as they relate to causes and cure? The best talent of the medical profession and the best statemanship the country affords should be represented on such Commission, and the best facilities which the Government can provide should be given it; and then its labors should be consecrated by a devotion to science, philanthropy and patriotism superior to all mercenary and party considerations. Let us have a *Commission on the causes and the cure of inebriety.*

### XI. International Medical Congress.

In consequence of the sanitary condition of several of the European States, which prevents their medical men leaving home, and, following the advice of many prominent scientists, both Italian and foreign, the Executive Committee of the above Congress has decided, by a large majority, to postpone the meeting till April, 1894. The exact date of the Inauguration will soon be fixed.

# ABSTRACTS.

## EARLY TREATMENT OF THE INSANE.

In a paper read before the American Medical Associations on this subject Dr. D. R. Brower states that he desires to call attention to this important topic before this learned and experienced body hoping to give rise to a discussion that will result in great benefit to the general practicioner by marking out the most useful line of practice for the insane, in the first stage of their disease. It is well to make the statement emphatic that the great majority of insane require as speedily as possible that peculiar care and treatment which can only be had in a well-organized hospital for the insane, but there must necessarily be in every case delay of a few days or a few weeks before the necessary arrangements, legal and otherwise, can be made that will secure for them this desirable treatment, and in this paper we propose to consider what shall be done for them during this period.

Some cases of insanity undoubtedly have their origin in auto-infection, and the violence of the manifestations, and sometimes the duration of the disease, can be modified favorably by careful attention to gastro-intestinal disinfection; so that it is well for the attending physician to carefully investigate the condition of this important canal. Colonic flushings with boracic acid, creolin, or even with sterilized water, and the internal adminstration of salol, salophin, the salicylate of bismuth, or some other gastro-intestinal disinfectant may be most judicious treatment. Some cases of insanity undoubtedly owe their origin to faulty elimination by the kidneys, bowels, and skin. It is therefore the duty of the family physician to investigate the condition of the renal secretion, not only as to the question of the presence of albumen and sugar, but as to total solids in the urine, and the relief of these conditions by appropiate treatment, alkalies and colchicum if you please, will sometimes improve the mental condition of these patients. Insufficient elimination by the bowels is a very common accompaniment of insanity in its various forms, and laxatives and enemas are often indicated and should be early administered. Cascara sagrada, the occasional use of calomel from three to five grains at bed-time, followed by a saline laxative in the morning, various laxative waters and after free evacuation of the bowels, then gentle impression on the tract by alœtic preparations will correct the intestinal insufficiency. The condition of the skin is often very deficient; warm baths, wet pack, and judicious massage will stimulate the functions of this important emunctory and be of service to the patient.

The attending physicians should give early attention to the question of feeding. In cases of mental depression, as well as in cases of mania, especially in the former, the amount of food consumed is altogether inadequate to maintain the ordinary nutrition of the body, much less to correct the deficient nutrition upon which the insanity often depends, and if the patient cannot be induced to eat by persuasion a liberal amount of food highly nutritious and easily digestible, early resort should be had to nutritive enemas, supplementing the insufficient food taken by the mouth by pre-digested foods used as enemas, and if the state of the mind of the patient is such as not to permit the use of these two methods of feeding, then early resort should be had to forcible feeding, by the nose, and this is so easily accomplished by the physician and his trained nurse, that it should not be omitted under the circumstances indicated. This forcible feeding should be done at least twice in 24 hours, and the largest quanity of the most nutritious combination of foods should be thus administered. Milk, cream, eggs, beef extracts, extract of malt, alcohol or some of its preparations, and such medicines as the patient may require, may thus be made into a common mixture and administered. I know of no more important indication connected with this matter of first care and aids to the insane than to see to it thata superabundance of easily digestible and highly concentrated nourishment is supplied.

The next important consideration is sleep. Careful attention should be given to securing in a proper manner and in

proper quanity this valuable aid to treatment. In proper manner, by selecting such agents as do not disturb the general nutrition. In proper quanity, for it is bad practice to keep these patients constantly under the influence of any narcotic; the aim should be to secure only a reasonable amount of sleep in the twenty-four hours, as, for example, eight to nine hours. These are difficult considerations to secure and enforce, but they are of great importance. In its consideration it may be well to divide the cases clincally into those that are characterized in their beginning by depression and those that are characterized by exaltation. For the depressed cases certainly remedies of a depressive character are not indicated; therefore, I should object to the use of the bromides and chloral in the treatment of the insomnia in this class of insane patients. I prefer in these cases hyoscine hydrobromate a drug very easily administered, being tasteless; the dose can be easily administered in any ordinary article of diet without the patient being aware of it. Next to hyoscine hydrobromate I should place somnal as an efficient and not depressive sleep-producing agent, and I have found that the formula proposed by Dr. Spitzka of New York is a valuable one in the administration of this drug. He combines the somnal with glycerin and elixir of calisaya about as follows: Somnal, drachm iii; glycerin, drachm viii; elixir calisaya, enough to make four ounces. Dose, tablespoonful at bedtime. This may be repeated in from one to two hours.

Chloralamid and sulfonal are also excellent hypnotics. Opium is often a remedy of service in the early stages of melancholia. A good preparation of deodorized tincture of opium or codeine in full doses will not only often promote sleep, but will relieve the patient of the intensity of mental anguish during the twenty-four hours if given in repeated doses. If these several remedies fail to produce sleep in melancholia, it may be neccessary to adminster chloral hydrate. If so, the chlorate hydrate should be guarded in its depressing influences upon the circulation by the administration with it of either hyoscine hydrobromate, the tincture hyoscyamus, or the tincture cannabis indica.

In producing sleep in ordinary conditions of the exalted type of cases, a combination of the bromides with chloral hydrate will usually give the best results. From 15 to 10 grains of the bromides, potassium or sodium, with a like quantity of chloral hydrate, repeated, if necessary, every hour, will in from one to three doses produce a sound and refreshing sleep, especially if the soothing effects of these remedies have been preceeded by a hot bath with a cold compress to the head. In some of these cases of mania a combination of sulfonal with potassium bromide will sometimes produce even better sleep with less depression the ensuing day than a combination of bromide with chloral. Chloralamid and potassium bromide, 15 grains each, is sometimes a good combination to produce sleep in cases of mania. This produces even less mental disturbance the following day than either of the combinations already mentioned. Where there is in mania feebleness of the capillary circulation, it is well to add to any of these combinations that may be selected full doses of the tincture of the cannabis indica, sleep then following with less disturbance of the general nutrition.

In some forms of insanity it may be necessary for the physician to fulfill some special indications of treatment, as in puerperal insanity. It is here the duty of the attending physician to carefully consider the condition of the uterus and its annexes. These important organs may require special treatment, the condition of the lochia requiring disinfectant treatment, not only of the vagina, but of the uterus itself. The condition of the breasts should also be looked into. In the forms of insanity that develop out of puberty, various sexual derangements are especially to be considered. Masturbation both in young men and young women is probably not a cause of the insanity, but a consequence of it, and yet every possible method should be resorted to to prevent it. The laity are especially concerned about the suppression of the menses, the popular opinion being that suppression of the menses has been the cause of the insanity. While suppression of menses may, by stopping this wonderful purifying process in women, causing the retention in the body of excrementitious material, thereby intensifying the insanity, and the restoration of the menstrual epoch, if it is possible, might be of service to the patient, yet, as a rule, a the suppression of the menses is not causitive

but consequential, and they will continue suppressed until the functions of the central nervous system have been restored; and the effort that is often made by the attending physician, urged by friends of the patient, to administer remedies that are supposed to have effect in retoring menstrual function is of serious injury to the patient. Very many of the laity think that travel is of benefit, and they urge this treatment but I am convinced that it is exceptional that any benefit arises therefrom. When the patient is improving, however, when restoration is under way, then judicious traveling is often a wonderful aid towards the rapid consummation of recovery. — *Medical Standard.*

## NATIONAL HEALTH SERVICE.

Gratifying to every sanitarian as must be the success of Surgeon-General Wyman in securing the co-operation of the State Health Officers, under the new quarantine law, it is none the less evident that the census of medical opinion throughout the country is that a more comprehensive law is necessary.

The reports of the committees of the American Medical Association and of the New York Academy of Medicine urge national legislation to the same end, but by widely different methods. That of the Association is persistent, though twice refused consideration by the Senate Committee of Epidemic Diseases and generally disapproved by practical sanitarians.

The proposed bill by the Academy is surprising, considering the committee, some of the members are well recognized sanatarians known to be familiar with state and national sanitary efforts. It comprehends the same discordant and ultimately destructive elements of the whilom National Board, and almost ignores the State Boards of Health—leaves their recognition to the President of the Commission—and seems by elaborateness to provide against their necessity.

We believe that a much better proposition would be:

That there shall be established within the Treasury Department a National Board of Health, to consist of seven members, all of whom shall be sanitary scientists, appointed by the President, by and with the advice of the Senate, shosen one each from the Judicial Districts of the Supreme Court, who shall devote the whole of their time to the duties of their office, and who shall receive salaries of five thousand dollars per annum. There shall be an Advisory Council of the Board, consisting of the Surgeon-General of the Army, Surgeon-General of the Navy, and the Supervising Surgeon-General of the Marine Hospital Service, and the Executive Officers of the State Boards of Health, who shall be required to meet with the National Board at least once a year, and as much oftener as the President may direct for council and advice; but the members of the Advisory Council, being salaried officers, shall receive no compensation other than their travelling expenses.

That the members of the Board shall meet at such time and place as may be designated by the Secretary of the Treasury, and organize by the election from their own number of a President and Secretary; and the Board shall proceed to appoint and equip bureaus or special departments and make all needful rules and regulations for their control, and for the guidance and discipline of all their employes; and shall establish all rules and regulations for the government of national sanitation in its interstate and international relations, in the enforcement and provisions of this Act.

All questions of law shall be referred to the Department of Justice.—*Sanitarian.*

## SALOL AS AN INTESTINAL ANTISEPTIC.

Dr. E. Mansel Sympson states in *The Practitioner* for August 1893, that the action of salol in the human body is now well known and is briefly as follows. After having been swallowed and passed through the stomach unchanged, it is split up in the duodenum by the pancreatic juice into its constituents, salicylic acid and carbolic acid. Their action will be alluded to more in detail later on, but it may here be said that they are thrown out of the body partly by the kidneys (the urine not infrequently being blackened by the carbolic acid) and partly by the intestinal tract in the fæces. And from experiments on dogs whose pancreases have been extirpated, there seems to be reason to think that salol can be absorbed from the intestine without the intervention of the pancreatic juice. As to its action on digestion there are different opinions, some authorities say that it unsettles the digestive processes, and that it actually sets up gastric trouble. These statements refer to its action in typhoid fever, which will be mentioned presently; other observers have however noted directly the contrary results. I have personally taken salol in five-grain doses three or four times a day, both before and after meals, when I have been perfectly well, without experiencing the slightest interference with digestion or appetite. The following experiments will show, however, that salol does appreciably affect the different digestive ferments so far as regards their rate of action.

*Experiment 1.*—Ten grains of arrow-root were boiled in two ounces of distilled water, cooled down to 100° F., and ten minims of Bleasdale's pancreatic essence added. The solution became perfectly clear. When one grain of salol was added before boiling, the starch required twice the amount of pancreatic essence, and an hour's more time (being kept at the same temperature), before the conversion was complete. If the salol was merely added with the essence, it made no difference. The same results followed, only less marked, from the use of half a grain of salol.

*Experiment II.*—Five grains of boiled and finely chopped up white of egg were pounded up with the following mixture: Benger's liquor pepticus twenty minims, dilute hydrochloric acid ten minims, and two ounces of distilled water. For four hours this mixture was kept at a temperature of 100° F. The albumen had entirely disappeared, and the mixture gave evidence of containing peptones. The addition of half a grain of salol checked the process considerably, at the end of the same time there were several fragments of egg undissolved, and two or more hours were required for complete dissolution. Both these sets of experiments were frequently repeated and the results were distinct and constant. [1]

Before finishing this brief account of salol, it may be said that it has been accused of producing herpes, and of increasing the delirium which frequently occurs in the course of typhoid fever. I have not noticed this latter myself either in that complaint or when I have used salol in cystitis.

In normal digestion the semi-digested acid chyme is poured out from the pylorus into the small intestine, to be exposed to the influence of the bile and pancreatic juice. These complete the digestion of the various food-stuffs, and some of the products of this digestion are due to the micro-organisms which are present in the intestine. Their work seems to be modified or kept in check by the presence of bile, for, as Foster remarks, "Bile possesses some antiseptic qualities. Out of the body its presence hinders various putrefactive processes; and when it is prevented from flowing into the alimentary canal, the contents of the intestine undergo changes different from those which take place under normal conditions, and leading to the appearnce of various poducts, especially of ill-smelling gases." [2]

The stomach undoubtedly is responsible for some cases of dypepsia, where the chyme is passed on to the intestines in an imperfectly prepared manner, which produces duodenal disorder. But in the

1 Similiar experiments made with salicylate of sodium showed that this drug had no action in pancreatic digestion, but about the same as salol in peptic digestion.

2 Foster's *Physiology*, 1889, p. 425. Also see a very interesting paper by Professor C. S. Sherrington, "The Escape of Bacteria with the Secretions," *Journal of Pathology and Bacteriology*, February 1893.

following class of cases we have, I think, evidence that occasionally the secretion poured into the intestine are at fault. The patient is probably of a "bilious" temperament, he may have a clean tongue with great loss of appetite and consequent loss of flesh; no pain during a meal, but coming on about two and a half to three hours after. Very likely he is constipated and when his bowels are relaxed the motion is greyish white. As a rule, he will not suffer from nausea, only a little retching sometimes, and instead of the gas being acid, as it so often is, it may be quite alkaline and 'soapy,' as a patient once told me. The seat of pain is the lower part of the abdomen, and is relieved by passing wind. There will perhaps be a slight yellowness, hardly amounting to actual jaundice. These cases belong, I believe, to the same class as those described by Dr. Allchin in his lectures on duodenal indigestion. I also believe that the symptoms are due to excessive and faulty fermentation in the small intestine owing to alteration in character and amount of the ordinary digestive fluids, more particularly of the bile. I have given dilute nitrohydrochloric acid to these patients, sometimes combined with liquor pepticus, to help the stomach to do its work properly; but it has made little or no difference in their condition. And opium in any form by the mouth has not given that speedy relief which it does in gastric affections. So, latterly, I have been in the habit of beginning with four or five grains of calomel, and following it in an hour or two's time with ten-grain doses of salol every four hours. This, to use the language of a somewhat enthusiastic patient, "acts like a charm" when taken about one and a half hours after meals. The pain ceases, the swelling of the abdomen does not appear, the appetite improves, and more important still, the wasting (due, I presume, to the non-digestion of a large part of the food) departs.

Another complaint wherein I have found salol exceedingly useful is a form of infective diarrhœa. Some months back I saw a family in a village near Lincoln who all had diarrhœa, passing dark-brown watery stools five, six, seven, or eight times in the twenty-four hours, attended with severe abdominal pain. In a few days several of the inhabitants of the village were seized with the same complaint, and every one had been into the first-mentioned house. Several more got it from the second source of infection. I regret that I was unable to discover any probable origin of the disease. I tried opium alone in some of the cases, but its action was far inferior to that of salol, whether combined with opiates or not.

In cases of ordinary diarrhœa, too, there are few remedies which more speedily check the flow and the pain than two-grain doses of salol. Some years ago, in the *Lancet*, I advocated giving glycerine of borax in the diarrhœa of infants, believing that undue fermentation in the intestines was the *fons et origo mali*. It does answer well, as I have over and over again seen; but I prefer in the severer cases to use salol in doses proportionate to age, as being a little more certain, more antiseptic, and almost as agreeable to take.

Lastly, I have been using salol exclusively in typhoid fever, not so much on the idea of combating the specific poison, but of cleaning and keeping clean the intestinal tract, and so subduing the irritation of the glands of Peyer's patches and other ulcers there, and that caused by the secretion from these ulcers in the intestine. Salol also prevents the excessive formation of wind, which is sometimes such a vexatious trouble to the patient. Salol brings the temperature down generally one or two degrees, causing abundant perspiration (this can be readily combated by giving oxide of zinc, tincture of belladonna, and some quinine in a mixture), reduces the number of stools from twelve or fourteen in the twenty-four hours to three or four, and when they are offensive, deprives them of any odor whatever. No bad effects were noticed with regard to its action in producing delirium. Its use was continued in typhoid fever for about a week after the disappearance of diarrhœa. It was always given in ten-grain doses suspended by means of compound tragacanth powder, at first (in typhoid fever and other complaints) every few hours, then every six, and for the last week three times a day. It was always given after food.

## WHAT IS THE VALUE OF THE SALICYLATES IN RHEUMATISM?

Many members of the profession will at once answer the question which heads this editorial in favor of salicylates. Yet there are others, who are able to quote large statistics and wide clinical experience, who will state that they believe that the general confidence in the value of the salicylates in acute articular rheumatism is not justified by the results which are obtained from its administration.

Probably the correct solution of this mooted point lies in the subdivision of the action of salicylates on the various parts of the body. Under such circumstances there is no doubt that the universal experience has been that salicylic acid or its salts produces a subsidence of the pain and swelling in the joints which are affected by acute articular rheumatism, and that this result may be accomplished after but three or four doses, or certainly by the third or fourth day. On the other hand, the collective investigation committee of the British Medical Association found that the average duration of pain was a little over ten days, while a collection made from the cases treated in the London hospital barely exceeded five days. Be this as it may, the results of both these investigations, which aggregated something like twelve hundred cases, showed that the drugs caused an amelioration of the joint-symptoms. Similarly, salicylic acid produces reduction of the fever, and in many instances the febrile process, under its influence, only persists for two or three days. On the other hand, it must be remembered that every now and then we meet with cases in which the joint-symptoms and the fever resists all doses of the salicylates which we may give within the limits of safety.

So far, then, we may consider that on general principles two of the important symptoms of acute articular rheumatism are relieved.

On the other hand, there are certain complications, which are so frequent and occur so early that they may be considered as symptoms or a distinct part of the disease, in which salicylic acid probably effects but little, namely, the appearance of cardiac manifestations of the action of the rheumatic poison. Of course, it is true that salicylic acid, by shortening an attack of rheumatism, in that way indirectly protects the heart; but, at the same time, there is no evidence that it protects this organ from the actual presence of the disease process. In other words, it may prevent cardiac disease indirectly, but its administration in no way preserves the cardiac apparatus intact while the febrile symptoms last. This has been pointed out in a number of the standard works on medicine, and should be universally recognized by the profession, even though all its members may not be willing to admit that the statement is entirely true. Thus, in Stewart's article in the "System of Therapeutics," he points out that Hood, of London, in the treatment of twenty-two hundred cases of acute articular rheumatism appearing in both sexes under thirty-six years of age, noticed that there were a very large number of instances in which cardiac disease was produced. Thus, of eight hundred and twenty-eight cases treated without salicylates, five hundred had cardiac disease, whereas in three hundred and twenty-eight cases treated with salicylates, one hundred and ninety had cardiac disease; or again, of three hundred and sixty cases treated with salicylates, two hundred and forty-one had complications, and in another series three hundred and sixteen suffered from cardiac disease out of a total of five hundred and fifteen. In other words, in all cases treated by salicylates the aggregate of cardiac complications was somewhat over sixty per cent., while those who were treated by other measures had cardiac complications in a little less than sixty per cent. It is, therefore, evident that the salicylic compounds are no more affective in avoiding these unfortunate manifestations of the rheumatic poison than are the various other modes of treatment. This point is emphasized, too, by the fact that the percentage of cardiac disease in cases treated by the salicylates is about the general percentage of cases, namely, between fifty and sixty per cent. It is also true that relapses seem to occur more frequently under the salicylates than under the older methods of treatment; perhaps because, when the older methods are used, the dis-

ease runs its course, or, as it were, exhausts itself, whereas the salicylates may alter its course before the system is thoroughly rid of the rheumatic poison.

To quote Stewart again: "Garrett has shown that the salicylates seem to have more effect upon the hyperemic group of symptoms, as, for example, those manifested about a joint, than upon the fibrous symptoms, as, for example, those seen in endocarditis."

There are other points which might be discussed in regard to the value of salicylic acid in rheumatism, but these are, after all, the most important. In view of the recent studies of Haig and those of other investigators who have not been so thorough in their methods of research, we cannot doubt that this class of compounds, uniting with the uric acid, produce salicyluric acid, which is readily eliminated, and so directly or indirectly result in the amelioration of the rheumatic symptoms.

It is hardly in place to consider the disadvantages which salicylates possess, so far as their untoward symptoms are concerned. That they are capable of producing disagreeable symptoms everyone knows, but they probably do not cause difficulties to arise any more frequently than other drugs possessing medicinal power of great value. There are instances of very severe symptoms, but after all, these have been few and far between. Perhaps the most noteworthy of these are the ones reported within the last few years in the *London Practitioner*, where the use of what might be called a very moderate dose of the salicylates produced petechial eruption and retinal hemorrhages, which latter resulted not only in temporary but permanent blindness.

There are but two points in regard to the use of salicylates in rheumatism which, we think, should be particularly emphasized, and these are, (1) that the physician, after once deciding to administer these remedies, should give them in large doses or not at all, that is, to use no less than forty to eighty grains a day; (2) that if, after administering the drugs in this way, no amelioration of the symptoms of any note has occurred at the end of four or five days, that it is useless to continue this line of treatment, as little good will be exercised over the rheumatic process, and much harm will be done by saturating the patient with such irritants to the kidneys and stomach as are the class of the salicylates.—*Therapeutic Gazette.*

## DIFFERENTIAL DIAGNOSIS AND TREATMENT OF CHRONIC EAR DISEASE.

Mr. Marmaduke Shield, writing on cholesteatoma of the mastoid cells, remarks that the pathology of these tumors, or rather accumulations, seems rather confused. They are considered as neoplasms by some; by others as originating in desquamating epithelium; and by a few as concentric masses of inflammatory *débris*, containing cholesterine and amorphous material with fat globules and fragmentary cells. The unyielding nature of the confining walls largely determines the shape and consistence of these masses. It is especially necessary in the ear not to confound these growths with dermoid cysts. A dermoid cyst has a distinct capsule and usually contains hairs; a cholesteatomatous formation is merely bounded by condensed laminæ and contains caseating *dèbris*. The true cholesteatoma of the mastoid is not a neoplasm in the strict sense of the word, but is due to the accumulation of many generations of squamous epithelial cells, which are successively shed. The epithelium grows into the mastoid antrum or cells from the auditory canal or tympanum through an opening previously caused by carious and necrotic processes. The symptoms occasioned by such tumors are largely those of chronic mastoid disease, and exploration will detect their true nature. After free excision, efficient drainage of the resulting cavity is best carried out by removing the overlying bone far more thoroughly than is generally done. Soaking with alkalies or pancreatic liquor, followed by the use of the intra-tympanic syringe, is a useful

treatment for accumulations of this kind. These points are well illustrated by the following case: An anæmic young woman, whose early history was obscure, was admitted into Charing Cross Hospital for right facial paralysis, associated with suppurative middle ear disease, and apparently dependent upon it. The patient was extremely ill, drowsy and stupid. A scanty but fœtid discharge flowed from the right ear. The patient had suffered from ear disease since childhood, and had had a previous attack of facial paralysis which had passed off. She was quite deaf on the affected side, even to loud conversation, but the tuning fork could be long heard on the mastoid and the watch on contact. Her principal trouble was persistent headache. The right facial muscles failed to respond to faradism. On examination it was found that there was partial destruction of the membrane with granulations. A small discharging sinus existed behind the ear. The mastoid fistula was explored under ether. It just admitted a fine probe. Mr. Shield enlarged the opening, and a small spoon was passed into a cavity of considerable size, full of firm caseating offensive material, composed of *dèbris* and large flat cells with a quantity of cholesterine. Pulsation could readily be detected against the spoon, as though the cavity were bounded by the dura mater. Iodoform emulsion was injected, and freely escaped through the meatus. A full sized tube was introduced and the parts daily syringed with a solution of peroxide of hydrogen, with the most marked relief to the "head symptoms." Subsequently a more extensive operation was deemed advisable to obviate a persistent sinus. Mr. Shield exposed the mastoid region, and, taking the sinus as center, with mallet and gouge removed the outer shell of the large cavity. Working layer by layer, he opened a considerable cavity, which seemed to include the whole mastoid; and concentrically arranged layers of tough cheesy material were detached by scoops. When this had all been removed there remained a smooth-walled cavity the size of a walnut. There was a total absence of signs of caries. When the patient was eventually sent to a convalescent home the hearing for conversation was good, and her general health and intelligence markedly better.—*The London Lancet.*

## Diseases of the Spleen and their Importance.*

Dando, of Milano, 1893, had made a collection of statistics of extirpation of the spleen, numbering 102, with forty-six recoveries and fifty-six deaths. The number of deaths chiefly followed in cases of leukæmic spleen. In a collection of twenty-five cases death followed promptly. The results of extirpation in simple hypertrophy are also unfavorable; eighteen operations with eleven deaths. In the cases of splenic malaria, eleven deaths in twenty-three operations. The results of operation for floating spleen are usually favorable; seventeen operations with two deaths. The remaining nineteen operations were cases of abscess of the spleen, plain cysts, echinococcus, amyloid, sarcoma, lympho-sarcoma, obstruction of the spleen, making in all seven deaths.

In connection with this paper the author has removed the doubts raised against the extirpation of the spleen by Zoccariello and Fioraranti in the year 1549.

## Prickly Heat.

Dr. Pollitzer finds that in prickly heat the horny layer of the epidermis is swollen by imbibition of water, the rete Malpighii slighly œdematous and containing cystically dilated sweat ducts, the blood-vessels of the papillary layer gorged. His view of the etiology of prickly heat is that it develops on a skin soaked in perspiration and insufficiently supplied with fat. He recommends patients suffering from it in summer in hot climates to anoint the regions usually affected with a fat after the morning bath, the fat he advises being lanoline with the addition of a little almond oil. — *Jour. of Cut. and Gen.-Urin. Dis.*

# CURRENT LITERATURE REVIEWED.

THE ANNALS OF OPHTHALMOLOGY AND OTOLOGY

for April, commences with a paper by Charles Stedman Bull, M. D., on

**Gonorrhœal Irido-choroiditis**

With a report of two cases. The same line of treatment was pursued in both cases. "Ten grains of sodium salicylate were given every hour for nearly three days when signs of gastric irritation compelled the discontinuance of the drug. Hot fomentations were applied continuously to the eyes and a mixture of atropine and cocaine was instilled every two hours and three leeches applied to the temple. After an interval of twenty-four hours, potassium iodide in twenty grain doses was administered three times a day, combined with twenty grains of the bisulphate of quinine." Under this treatment the pain in the eye was rapidly relieved but as the potash soon disturbed the stomach it was discontinued. The local treatment was continued and a cure effected by giving salicylate of cinchonidia five grains every hour, which was well borne by the patient. Dr. Bull remarks that the disappearance of the iritis under appropriate treatment without leaving posterior synechiæ proves the absence of the plastic character. Its prompt disappearance distinguishes it also from the usual forms of serous iritis.

Dr. Charles W. Kollock of Charleston, S. C., contributes a very interesting paper on

**The Eye of the Negro**

He states that the eye of the negro is not so good as before the war. During the days of slavery the master engaged the best medical talent for his protection and every case was taken to preserve him in the best of health. But with the war came many troubles, many negroes were sent to work upon the fortifications which were constructed along the coast, troops from both armies camped in their midst and syphilis having thus a comparatively new field spread as fire on the prairie, carrying every thing before it, so that now it is scarcely an exaggeration to say that when you see a negro, you see a case of syphilis. "A careful inquiry among the older physicians proves that before the war these people had little or no eye trouble beyond cataract, that ulceration of the cornea, which now numbers its victims by the thousand, was almost unknown, and it is certainly very rare that nebulous cornea, iritic adhesions and eyes lost from ophthalmia neonatorum are seen among the older and ex-slaves, while among the younger, the post-bellum negro, such cases are not only of daily occurrence but steadily increasing." This is partially the "diseased condition of the people, who being now thoroughly syphilized, possess all the dyscrasias that may follow such a condition and present a most fertile soil for all ulcerating and wasting diseases. Not entirely to syphilis can all this be laid, but to their manner of living, poorly housed and clothed, and ill nourished. Parents are utterly indifferent to the condition of their children, allowing them to go months without treatment, or perhaps using the filthiest of domestic remedies. Blindness, or greatly inpaired vision, is seen on all sides from this cause, and the outlook is truly discouraging. Trachoma is comparatively rare among them, but so it is among the whites of Charleston and throughout South Carolina." Iritis is of very common occurence. Cataract is quite as frequently seen in the negro as the white. Retinitis, optic neuritis, and choroiditis are not infrequently seen in the eye of the negro, but retinitis pigmentosa has not been observed in the pure blood black. Xerosis conjunctivæ is in Charleston and vicinity, a condition peculiar to the negro, and especially the children, and as yet not a case has been observed among the whites. In many cases tonic treatment and good food will bring about a cure, while in others nothing seems to improve.

Referring to the refraction of the eye of the negro, the writer states that "he has never seen but three cases of myopia in the black negro, and though they were black in color, still the features indicated mixed blood, therefore in the pure-blooded negro he has never seen a case of true myopia." But a comparatively small number of pure bloods have been examined for refractive errors when their eyes were under the influence of a mydriatic. The vision has however been almost invariably tested, and in the great majority of cases was found to be normal unless some haziness of the media existed; and the ophthalmoscopic examination confirmed the fact that but few varied from the normal or emmetropic eye. Among the mulattoes a very different state of affairs exists.

The eyes of sixty negroes, blacks and mulattoes, have been recently examined, whilst under the influence of a mydriatic, for refractive errors; of the sixty examined eleven were black and forty-nine were mulattoes. Of the eleven blacks six were males. Four of the black men were emmetropic. Three of the black women were emmetropic, one was hypermetropic, and one had myopic astigmatism, Of the forty-nine mulattoes, seven were men and forty-two women; of the seven men four were hyperopic, three myopic. Of the forty-two mulatto women, one was emmetropic, twenty-one were hyperopic, seven myopic; eleven had hyperopic astigmatism and myopic astigmatism. The author concludes by saying "Undoubtly the eye of the negro is failing from three causes, viz.: Civilization, syphilis and education."

This paper is followed by one on

**Reflex Ocular Disturbance from Irritation of the Genital Organs.**

by Edward B. Patterson, A. M., M. D. of Michigamme, Michigan

Dr. John Dunn of Richmond, Va., reports one case and Dr. Howard McIlvain Morton, of Minneapolis, Minn., reports two cases of "Keratitis Dendritica." In Dr. Dunn's case more decided improvement was effected by the galvanic current applied to the closed lids than by any other treatment. In the cases treated by Dr. Morton aristol was dusted on the ulcers, and a solution of atropine and eserine was instillated. A satisfactory cure resulted from these applications.

---

THE ANNALS OF GYNECOLOGY AND PÆDRIATRY.

for August. Dr. M. Rosenwassar contributes a paper on

**What are the Indications for Abdominal Section in Intra-pelvic Hemorrhage?**

The author comes to the following conclusions:

1. Intra-pelvic hemorrhage may be free into the peritoneal cavity, or primarily or secondarily circumscribed by true or false membranes.

2. Though nearly always due to ruptured ectopic pregnancy, the same surgical principles underlying the treatment of other similar hemorrhages are applicable in intra-pelvic hemorrhage.

3. Such treatment must, however, vary accordingly to the conditions, dependent primarily on the hemorrhage, and secondarily on the original cause of the hemorrhage; hence,

4. To prevent free intra-pelvic hemorrhage, abdominal section is indicated in all cases of presumably recognized, unruptured tubal pregnancy, either as a prophylactic, or for the purpose of removing pathological conditions not otherwise curable.

5. In all cases of free intra-pelvic hemorrhage, from whatever cause, early or immediate section is the only safe means of averting a fatal termination.

6. In circumscribed intra-pelvic hemorrhage, section is indicated for removal of in creasing blood clot and debris, whether it be due to recurrent bleeding or continued growth of fœtus.

7. In circumscribed intra-pelvic hemorrhage section is necessary whenever the symptoms indicate decomposition of the blood clot.

8. Lastly, section is also indicated whenever the pressure of the circumscribed blood mass produces obstruction of the bowel.

Appended to the paper is the table of sixteen operations performed for intra-pelvic hemorrhage.

Dr. Wallace A. Briggs contributes a paper on

**The Obstetric Forceps.**

The indictment he brings against the ordinary obstetric forceps is, that its use demands an extravagant expenditure of force and attention with correspondingly diminished reserve and control. He proposes a modification of the present form in which the handles are shaped like that of a shovel and are detachable from the shaft, fitting two pairs of blades, long and short, and of an axis traction attachment in the form of a straight bar projecting at a right angle downwards from the main handles. The handles are made detachable for the purpose of facilitating the crossing of the blades and perhaps at times the introduction of the blades. The author states that these forceps have stood the test of practice. The points of superiority claimed for this instrument are: firm and comfortable grasp; economy in the expenditure of force and exactitude in its application; reserve force and consequent control.

**Uretero-vaginal Fistula following Vaginal Hysterectomy for Cancer of the Uterus.**

is discussed by Dr. L. H. Dunning. After reviewing the literature of the subject, the author presents the following conclusions:

1. Injury of the ureter during vaginal hysterectomy is liable to occur in the practice of skillful operators.

2. It is more likely to occur when there is broad ligament infiltration, or when there has been parametric inflammation, with adhesions.

3. Whether the use of forceps and clamps more frequently results in such injury and fistula than when ligatures are employed has not been determined, but such is probable.

4. In the five new cases the injury did not seem to have an unfavorable influence upon the immediate recovery of the patient. More observations are needed upon this point.

5. In cases of resulting ureteral fistula, disease of the corresponding kidney is prone sooner or later to appear, whether the fistulous opening be into the vagina or upon the surface of the body.

6. Operations for the closure of uretero-vaginal fistula, so that the urine will have an unobstructed and uninterrupted flow in the bladder, should in proper case be employed.

7. The operations of Parvin, Simon, Bandl, Landau and Gerde have this end in view, and should be employed in suitable cases if the kidney is healthy.

8. Kolpokleisis, either partial or complete, leaves an artificial receptacle for the urine walled in by tissue, in which we fear the speedy return of cancer, hence is of doubtful utility.

9. Nephrectomy is a justifiable precedure in uretero-vaginal fistula when there is obstruction to a free flow of the urine into the vagina that cannot be overcome by dilatation of the fistulous opening, in case of failure of plastic operation and when the corresponding kidney is markedly diseased.

**Salpingitis and Pelvic Adhesions**

is the title of a paper by Dr. H. G. Wetherill, in which the following conclusions are reached by the author.

1. Tubal and ovarian inflammations are usually associated; the one rarely being present without the other.

2. This tubo-ovaritis is nearly always the extension of a specific or septic inflammation along the mucous membrane, or through the lymphatic vessels.

3. That this implies an unclean vagina or uterine canal (in the modern surgical sense),

or that hands or instruments introduced into the genital tract have carried infection to it.

4. Abrasions and lacerations of the mucous membrane greatly increase the risk of tubo-ovaritis by lymphatic extension and by the facility offered for the growth of bacteria, and the difficulty of sterilizing wounds in such a situation.

5. Surgical cleanliness of all vaginal and uterine manipulations is imperative as a prophylactic measure. Labor at term and abortions must be followed by rigid antisepsis. Lacerations should be approximated at once when possible and abrasions kept perfectly clean.

6. Adhesions about an inflamed tube and ovary are conservative in design and effect, and should not be disturbed till the disease back of them is removed.

7. When the disease is removed the adhesions tend to absorption and usually disappear in time.

8. Septic infection is a more potent factor in causing adhesions than simple aseptic traumatism, and the adhesions following slight injury to the healthy peritoneum are due to mild infection, which may have taken place at the same time.

Dr. J. S. Hammond contributes a paper on "Puerperal Eclampsia" advocating the use of veratrum viride in doses of thirity to forty drops of Norwood's tincture hyperdermically.

Dr. Alexander J. C. Skene discusses the "Pathology and Treatment of Injuries of the Pelvic Floor." A review of his paper will be found in THE MEDICAL AND SURGICAL REPORTER for August 19, 1893, page 306.

The remaining papers in the issue are: "Catheterization of the Ureters," by Dr. Howard A. Kelly; "Dilatation of the Cervix for Dysmenorrhœa," by Dr. Edmund M. Pond; and, in the Pædiatric Department, an interesting paper by Dr. William D. Wirt on the "Conservative Treatment of Joint Diseases."

# PERISCOPE.

## MEDICINE.

### Th Forms of Diabetes.

Dr. George Harley gives the following classification of diabetes:

1. Hepatic diabetes—including the gouty variety.
2. Cerebral diabetes—including all cases of saccharine urine arising from nerve derangements.
3. Pancreatic diabetes—the most deadly form of the disease.
4. Hereditary diabetes—a form by no means uncommon, and one, too, where both brothers and sisters may labor under the disease without either their maternal or paternal parent having been effected by diabetes, though more distant members of the family may have suffered from it.
5. Food diabetes—including all forms of saccharine urine arising from the ingestion of unwholesome substances.

In the matter of treatment, besides diet and opium or codeine, Dr. Harley recommends croton chloral, strychnine, phosphoric acid for thirst, and an absolute prohibition of alcohol—*Med. Record.*

### Hot Water in the Treatment of Corneal Affections.

Dr. J. A. Lippincott (*Ophthalmic Review*) recommends the repeated instillation of water at a temperature of about 150° F., applied directly drop by drop, to the affected area in obstinate corneal ulcers and in suppuration after corneal wounds. He details one case in which this method was very effectual, and refers to others in which he has been satisfied with its results. He advises that the water be heated in a test tube, or some other vessel, in order to secure a certain temperature, and then transferred by means of a dropper and applied as before described.

### Gastric Ulcers and the Consequent Symptoms of Irritation.

Prof. Wilhelm Fleiner (*Munchener med. Wochenschrift*) writes concerning the results of injections of large quantities of bismuth subnitrate through the stomach-tube in case of ulcer, and the various painful or intolerant conditions of the stomach arising from ulcer or cancer. The indications are:

1. In all sensitory, motor or secretory signs of irritation of the stomach in which simple lavage is not sufficient, as in old ulcers, ulcerating carcinoma or hemorrhagic erosions.
2. As a specific remedy in gastric or duodenal ulcer.

The bismuth is to be used daily at first, then with decreasing frequency. The dose is 150 to 200 grains suspended in lukewarm water. When the stomach-tube cannot be used, the same may be drunk from a tumbler. It is contradicted where there is much decrease of HCl, except in ulcerating cancer and hemorrhagic erosions.—*Lancet Clinic, Cincinnati.*

### Vaseline in Certain Affections of the Middle Ear.

Dr. Delstanche (*Le Bulletin Medical*, No. 8, 1893) speaks highly of injections of liquid vaseline in adhesive affections of the ear. He injects it through the Eustachian tube into

the tympanic cavity. It is perfectly innocuous, and from an experience extending over several years he finds it of value:

1. To rupture extensive adhesions of the tympanic membrane with the wall of the labryinth where insufflation of air, etc., are found insufficient. He has had several cases of partial success with forced injections of the liquid vaseline.

2. To clear out mucous accumulations from the tympanum during the course of certain chronic catarrhs. It forces the mucus into the mastoid cells, where it no longer interferes with hearing, or into the pharynx.

3. To diminish the chances of inflammatory reaction after paracentesis of the tympanum, where the matter filling the tympanum is dense or viscid, and will not evacuate itself spontaneously in a satisfactory manner. Here, from its innocu ity, it is to be preferred to any other liquid.

4. To open an obstructed Eustachian tube when mucus blocks it and prevents insufflation of air, a few drops of vaseline blown through the catheter will clear it at once. Hence this simple means is always to be tried before dilatation with sounds is attempted.

5. Finally, in acute inflammation of the middle ear, either with or without perforation, especially in purulent otitis complicating influenza, massive injections of liquid vaseline saturated with iodoform render signal service, from their sedative action upon the atrocious pains which often accompany this affection. They also appear to hasten and aid to a favorable termination.

### Pilocarpine in Elephantiasis.

Dr. Poulet (*Med. Neuigkeiten*, No. 7, 1893), in a case of elephantiasis involving one leg, obtained a lasting and considerable decrease in size of the member by subcutaneous daily injections into the limb of 1 to 2 dgm. doses of pilocarpine. This treatment was continued through several months.—*Pritchard.*

### Phenacetin Poisoning.

The following case, illustrating some effects of phenacetin, is of interest in view of the rapidly extending use of this drug among the general public; it is recorded by Eisenhart. A strong and healthy man, thirty-two years of age, was given for neuralgia proceeding from a carious tooth antifebrin in doses of about seven grains, with no result except the appearance of a swelling about the size of a hazel nut on the jaw. Phenacetin was then given in two doses of fifteen grains each in the morning and in the evening with two hours' interval. The effect was satisfactory: not only did the pain in the branches of the fifth nerve disappear after the second powder, but the swelling became less, only some dull pain in the tooth remaining. To remove this, the patient took on the following evening three powders—one at five o'clock, the second at 6.30, and the third about eight, shortly before supper. About nine o'clock he was seized with palpitation, increase of the action of the heart, and a certain oppression of breathing, more especially in speaking. These symptoms remained without variation for half an hour, when they suddenly increased: the oppression became more intense, palpitation rapidly got worse, deafness was manifest, and evanescent hot flushing with outbreak of perspiration, sickness and vomiting. With the sickness every trace of poisoning passed away entirely, and the patient felt quite well.—*Therap. Monat.*

### Some Drawbacks of Borax in Epilepsy.

Now that borax is so much employed in the treatment of epilepsy it is well to remember that, when it has been long continued, it causes, as noted by M. Lemoine Georges of Lille, a peculiar disease of the gums like that seen after lead. Diarrhœa and skin eruptions are also mentioned by Dr. Gowers as disagreeable and not infrequent effects. It is desirable to begin with small doses, such as fifteen grains daily.—*Med. Chron.*

### Crying in Children.

The cry of children, according to Dr. E. C. Hills in pneumoina and capillary bronchitis is moderate and peevish and muffled, as if the door were shut between child and hearer. The cry of croup is hoarse, brassy and metallic, with a crowd inspiration. That of cerebral disease, particularly hydrocephalus, is short, sharp, shrill and solitary. Marasmus and tubecular peritonitis are manifested by moaning and wailing. Obstinate, passionate, and along-continued crying tells of earache, thirst, hunger, orginal meanness, or the pricking of a pin. The pleuritic is louder and shriller than the pneumonic, and is evoked by moving the child or on coughing. The cry of intestinal ailments is often accompanied by wriggling and writhing before defecation. Exhaustion is manifested with a whine. Crying only, or just after coughing, indicates pain caused by the act. The return or inspiratory part of the cry grows weaker toward the fatal end of all diseases, and the absence of crying during disease is often of graver import than its presence, showing complet exhaustion and loss of power. Loud screaming sometimes tells of renal gravel.—*Ontario Med. Journal.*

### The Treatment of Hemorrhoids by Electricity.

Bacon employs the following methods, which in all of his cases caused a decided decrease in the tumors, without secondary hemorrhage, sloughing or after-pains. He makes use of an instrument consisting of a long pair of forceps, similar to urethral forceps insulated with vulcanized rubber, except at a place one-half an inch in length on the face of the blades. By means of a binding screw the forceps can be connected with the positive pole of a battery. The hemorrhoid is seized with the forceps in such a manner as to have the exposed metal of the blades clasp it at its base. The negative pole is connected with a disk or needle-holder, pre-

ferably one containing four needles. After grasping the hemorrhoid with the forceps, a few drops of a 4 per cent. solution of cocaine are injected into the tumor. The needles are then pushed into the center of the tumor, and a current of from five to ten milliamperes turned on. Immediately there will be noticed an escape of hydrogen about the needles, and a decided blanching of the pile. The current should be kept on until the tumor becomes a whitish gray, usually requiring from two to five minutes of time.

There are some points necessary to observe in using eloctrolysis in this class of cases: Thoroughly empty the colon before operating. Disinfect the tumor before introducing the needle. Never use this method in acutely inflamed hemorrhoids. The needles should be boiled before using.—*Univ. Med. Mag.*

### Transfusion of Nervous Tissue in Neurasthenia.

To the French Academy of Medicine M. Constantin Paul reports the results of the treatment of sixty-one cases of neurasthenia by the injection of the grey substance of the cortex of the sheep diluted with water. In fifteen cares there have been no results; in forty-six there has been more or less success. Of these fifteen cases eight had not given the treatment a long enough trial; four were hypochondriacs who are very little amenable to any treatment. There had been sucess in some cerebro-spinal cases, in one spinal case, in some cases of impotence, in some of chlorosis, in some of neurasthenia at change of life, in some in old age, and in other cases during chronic uterine disease. There had been improvement in sleep, in mental activity, and in cardiac strength. In the commonest cerebro-spinal forms the general plan of treatment had been to give twenty injections during eight or ten weeks.—*Le Progres Med.*

## ARMY AND NAVY.

U. S. ARMY FROM AUGUST 13, 1893, TO AUGUST 19, 1893.

Leave of absence for one month, to commence about September 1st, 1893, is granted Captain M. W. Food, Assistant Surgeon U. S. Army.

By direction of the President the retirement from active service this date, by operation of law, of Lieutenant Colonel John H. Janeway, deputy surgeon general, under the provisions of the act of Congress approved June 30, 1882, is announced.

Leave of absence for one month, to take effect when relieved by another medical officer, is granted First Lieutenant Harlan E. McVay, assistant surgeon, San Carlos, A. T., with permission to apply for an extension of fifteen (15) days.

Major Henry R. Tilton, surgeon U. S. Army, is granted two (2) months leave of absence, when relieved from duty at Fort Wayne, Michigan.

U. S. MARINE HOSPITAL SERVICE FOR THE EIGHT WEEKS ENDED AUGUST 5, 1893.

Fessenden, C. S. D., Surgeon, to proceed to Mobile. Ala., for duty June 16, 1893. To proceed to New Orleans, La., as Inspector, Aug. 1, 1893.

Murray, R. D., Surgeon, granted leave of absence for seven days, June 21, 1893.

Vansant, John, Surgeon, to proceed to Wilmington, N. C., for duty June 16, 1893.

Austin, H. W., Surgeon, to inspect Delaware Breakwater Quarantine Station, July 22, 1893.

Gassaway. J. M., Surgeon, to proceed to Detroit, Mich., and Chicago, Ill., as Inspector, July 12th, 1893.

Irwin, Fairfax, Surgeon, detailed for duty in Office of the U. S. Consul, London, England, July 2nd, 1893.

Carter, H. R., Surgeon, to proceed to Brunswick, Georgia, for temporary duty. June 28th, 1893.

Peckham, C. T., Passed Asst. Surgeon, granted leave of absence for six days, June 22, 1893.

Brooks, S. D., Passed Asst. Surgeon, granted leave of absence for three days, June 22, 1893.

Carrington P. M., Passed Asst. Surgeon, detailed for duty in office of U. S. Consul, Bremen, Germany, June 15th, 1893.

Kinyoun, J. J., Passed Asst. Surgeon, to rejoin Station, Washington, D. C., July 10th, 1893. To inspect Camp Low, New Jersey, July 29th, 1893.

Goodwin, H. T., Passed Assistant Surgeon, granted leave of absence for three days, June 12th, 1893. To proceed to Louisville, Ky., for duty, July 12th, 1893.

Vaughan, G. T., Passed Asst. Surgeon, to proceed to Chicago, Ill., for temporay duty, July 10th, 1893.

Geddings, H. D., Passed Asst. Surgeon, to proceed to Delaware Breakwater Quarantine for duty, June 30th, 1893.

Perry, J. C., Passed Asst. Surgeon, to proceed to Portland, Me., for temporary duty, July 8. 1893.

Stimpson, W. G., Asst. Surgeon, detailed for duty in Office U. S. Consul, Glasgow, Scotland, July 7th, 1893.

Gardner, C. H., Asst. Surgeon, granted leave of absence for fourteen days, July 19th, 1893.

Strayer, Edgar, Asst. Surgeon, to proceed to Vineyard Haven, Mass., for temporary duty, July 8, 1893.

Oakley, J. H., Asst. Surgeon, to proceed to Wilmington, N. C., for temporary duty, June 24th, 1893.

Norman, Seaton, Asst. Surgeon, granted leave of absence for three days, July 24, 1893.

Branham, J. W., Asst. Surgeon, to proceed to Brunswick, Ga., for temporary duty, July 25, 1893.

Sprague, E. K., Asst. Surgeon, granted leave of absence for fifteen days, July 22nd, 1893.

Prochazka, Emil, Asst. Surgeon, relieved from duty at Ellis Island, N. Y., and ordered to report to Medical Officer in command, New York, N. Y., July 29th, 1893.

GRANULAR EFFERVESCENT

**BROMO LITHIA**

(WARNER & CO.)

Each dessertspoonful contains

℞ Salicylate Lithia, 10 grs.,
and Bromide Soda, 10 grs.

A remedy in the treatment of

**RHEUMATISM, GOUTY DIATHESIS, ETC.**

Dr. A. Garrod, the well-known English authority on Gout, who was the first physician to introduce the Lithia Salts in the treatment of the gouty diathesis, states that their action is materially increased by being administered in a *freely diluted form*.

This effervescing salt of Lithia furnish an easy and elegant way of applying Dr. Garrod's methods.

PREPARED ONLY BY

**WM. R. WARNER & CO.**

For Nervous Headache and Brain Fatigue.

WARNER & CO.'S EFFERVESCING

**BROMO SODA**

(WARNER & CO.)

**Useful in Nervous Headache, Sleeplessness, Excessive Study, Over Brainwork, Nervous Debility, Mania, etc., etc.**

DOSE.—A heaping teaspoonful in half a glass of water.

It is claimed by some prominent specialists in nervous diseases that the Sodium Salt is more acceptable to the stomach than the Bromide Potassium. An almost certain relief is given by the administration of this Effervescing Salt. It is also used with advantage in Indigestion, Depression following alcoholic and other excesses, as well as Nervous Headache. It affords speedy relief for Mental and Physical Exhaustion.

### THE TREATMENT OF DIPHTHERIA.*

R. A. PATTERSON, M. D., Aurelian Springs, N.C.

The constant discovery of new remedies, the new applications of old ones and the appalling fatality of some visitations of diphtheria, even at this day of advanced medical knowledge, seems to justify the effort to cast upon it every ray of light possible, even at the risk of much repetition.

If it be claimed that the pathology, diagnosis and etiology of the disease are understood, the great diversity of systems of therapeutics offered by their various advocates, show that the best mode of treatment is far from being established, and should this priceless boon ever be granted, it must in turn reflect great additional light on the causes and pathology of diphtheria and thereby act as a prophylactic. Striving to reach this most desirable point, viz.: to determine the most successful mode of treating diphtheria, the writer would add another to the list of remedies, or rather a plan of treatment which has proved most efficacious.

Diphtheria has been described under various names from a remote period, the names being taken mainly from its visible effects. A fibrous deposit on certain mucous membranes characterizes the disease. The membrane may be merely attached to the mucous surface, or may infiltrate it and the tissues beneath. Some writers, however, claim that this difference is the proper distinction between diphtheritic and croupous deposits. They contend that when the deposit is superficial and does not infiltrate it is croupous, and when it infiltrates it is diphtheritic. The tonsils and neighboring parts are the regions mainly affected in the early stages, and as it is estimated that three-fourths of the fatal cases result from the invasion of the air passages, it should obviously be the object of the practitioner to arrest it ere it extends further. Experience proves that this arrest can be made, if treatment be begun early on the plan to be described. If not arrested, the membrane may spread to the larynx, trachea, bronchi, the nasal cavities, Eustachian tube, middle ear, the eye, involving loss of vision, the lips, or any of the outlets of the body, and in an epidemic may attack an ulcer existing on any part of the derma. The first distinctive sign, the grayish-white patch, may be preceded by slight inflammation. It may become reddish-brown and varies greatly in consistence. If the deep tissues are involved, the removal of the membrane frequently discloses ulceration. If not arrested early, the tonsils and adjacent parts become greatly enlarged. The microscope reveals bacteria, micrococci, pus cells, epithelial cells and red blood corpuscles in the fibrous membrane.

There is a difference of opinion as to the pathology of the disease. One view is that the vegetable germs find lodgment in the throat in the first instance, migrate to other parts of the body and so the disease becomes general. Another, that it is general from the beginning and that the local manifestations are secondary.

* Read before the North Carolina State Medical Society, May, 1893.

It is generally admitted to be contagious, and also to be produced by neglect of sanitary precautions. The contagion seems to be feeble in some instances, so as to lead to the denial occasionally of its being communicated in that way. Many striking instances, however, of its contagiousness, or at least of its portability, could be cited.

Now, it cannot be denied that from the pathology and symptoms, the antidote must be distinctly antiseptic and germicidal, also that it must be tonic and alterative. The disease is rapid in its course and the success of any line of treatment depends on an early application of the remedies, for if through delay it is allowed to enter the air passages, the chance of recovery is greatly lessened. Adopting this view and adapting this mode of treatment thereto, the phenominal success of it verifies its correctness and proves it to be founded on scientific principles and to be devoid of empiricism.

Before detailing the plan of treatment pursued, the outline of the history of some epidemics which came under the observation of the writer, extending back through years, will be premised.

In the autumn of 1886, an epidemic of diphtheria presented itself in a locality between Wildon and Loston, in the county of Halifax, whether through contagion or neglect of sanitary precautions did not appear. There were many fatal cases, in one instance three deaths in one family, and the attending physicians pronounced it to be of a most malignant type. The epidemic extended and entered the bounds of the writer's practice. The first case had most careful attention. The course of treatment was such as had been inculcated by reputable authors. In spite of every means it marched steadily on to a fatal termination. Before being called to another case the plan of treatment to be cited occurred to him, and in the twenty cases following there was not another death. In fact its course was nearly arrested, very few cases having occurred beyond, and these all terminated in health, the success in the twenty cases having induced the attending physician to adopt the same course. In the years next succeeding sporadic cases occurred from time to time which yielded readily to the same treatment.

In the autumn of 1892, the author was called to the case of a girl, aged about 12 years, who had been under the treatment of a practitioner for five or six days and declining steadily, till at the time I saw her, it is fair to say she was *in articulo mortis*. She died during the succeeding night. This case was followed by three others in the same family, but the early application of the remedies was so efficacious that it prevented the necessity of confining any one of them to bed. During the next week, in a family near-by where there were seven children between the ages of two and eighteen, the disease presented itself. Having been called to its treatment, and the mother being a woman of strong sense and a good nurse, the medicines were prepared, the directions given and the management of the cases was committed to her. She carried them all through safely without other medical advice. About the same time a case appeared in the person of a small boy of a neighboring family and the same course of treatment soon restored him. A neighboring physician, observing its action, adopted it and relates remarkable cases of recovery from its use.

We now come to the indications of treatment as suggested by its known attribute. It was stated above that germicides, tonics and alternatives have yielded the best results. Some years back in a prize essay by the late Dr. E. S. Gaillard, he warmly advocated a combination of muriatic acid, tincture muriate of iron and potassium chlorate, to be taken internally. This was a most fortunate conception. For this combination on the addition of water sets free much of that efficient and excellent germicide *chlorine*, and yields to the system the tonic iron so much needed in the asthenic condition of the system appertaining to this affection. It is a remedy highly approved by many and will of itself undoubtedly prove curative in some cases. But it fails in some instances. A combination of fluid extract of pinus canadensis and phenic acid, applied locally, has been much extolled. The pinus canadensis, as an application to inflamed and ulcerated surfaces, was highly commended by the late J. Marion Sims, and the writer in various affections has verified its claims as a curative. The addition to it of phenic

acid brings another powerful antiseptic to the aid of chlorine, and the septic tendency of the disease seems at once to yield to the potency of the two. Now, it occurred to the writer that if this constitutional remedy, as suggested by Gaillard, and the excellent local application of the pinus canadensis and phenic acid were used in conjunction, it would most probably arrest the rapid advance of the sepsis if applied early in the attack. The result, after long and thorough trial, verified his most sanguine hopes and in these two applications, constitutional and local, we have a remedy, a specific for diphtheria, if there is a specific for any disease. So that while the writer claims no credit as the discoverer of the disunited elements, he does claim to have first suggested, so far as he knows, the combination which seems to be the *ne plus ultra* as to the treatment of diphtheria.

The details of treatment are these: As soon as the patient is seen, and not delaying for the action of a cathartic or other medicine, begin to combat the poison at once by the administration of two tablespoonfulls every hour for adults, and proportionally less for children according to age, of the following preparations: Potassium chlorate one drachm; dilute muriatic acid two fluid drachms; tincture muriate of iron two fluid drachms; water twelve fluid ounces. Diminish to one or two doses at night, with tonic doses of quinine, three times a day. The above compound is not objected to much by children. Immediately after its administration, proceed to mop the throat, after depressing the tongue, with a mixture of fluid extract of pinus canadensis one fluid ounce, and phenic acid gtt. 10 to 15. The mopping is repeated after each dose of the solution. The mop may be made of a small twig with a little lint bound to the end. This simple implement is given instead of a more artistic one because so easily obtained. The mopping should be done so as not to wound the tender mucous membrane. Petroleum, applied externally to the throat, is advisable.

Under this treatment improvement begins at once. The fibrous matter ceases to accumulate. That which has already appeared turns black, being stained by the red pinus, contracts around the edges and in a few days drops off and amelioration of all the symptoms becomes obvious. Unlike the plan of treatment proposed by Dr. Martindale, of New York, at your last meeting, this course of treatment does not require an air tight room so difficult of attainment in many localities, or an oil stove quite as much so, but may be applied easily and speedily anywhere.

# CLINICAL LECTURES.

## MERCURIAL PTYALISM; HEPATIC ABSCESS.

CHARLES CARY, M. D., Buffalo, N. Y.†

The first patient whom I present to you this morning illustrates the condition of ptyalism, which is usually produced by the administration of one of the purer forms of mercury. The patient states that for two weeks before coming into the hospital, he had been rubbing a mercurial ointment into his arm. Just how much he has used we do not know, except that it was a boxful. It is not important, however, to know either the weight of the ointment or its strength, for the amount absorbed depends largely upon the faithfulness of the patient in carrying out the instructions to rub the ointment well into the skin, and upon the activity of the skin circulation, the thickness of the cuticle and other more obscure conditions. Again, there is a great difference in the susceptibility of different patients to the action of mercury. Ptyalism has been produced by a single vaginal irrigation.

When the patient entered the hospital, his tongue and lips were swollen, the cavity of the mouth could hardly be distinguished, the gums were tumid, softened

†Professor of Materia Medica and Therapeutics, and of Clinical Medicine, University of Buffalo.

and ulcerating, while the teeth and tongue were covered with sordies so that the breath was extremely offensive. The tongue is still covered with a creamy exudate, with the suggestion of ulcers at the side. Those of you who are near the patient can also notice the odor of mercurial stomatitis. One of the earliest symptoms of mercurialism is a sense of sticking together of the teeth. You must warn your patients who are taking mercury to be on their guard against this development. Direct them to strike the teeth together occasionally. As long as they meet firmly and without sensitiveness, the mercury is not being given in excess. If, however, the teeth seem to the patient to meet as if there were glue between them, or if they seem too long, as if forced from their sockets, the medicine must be discontinued, or, if it is a case of urgency, continued with caution. At this time fetor begins to be apparent. If the drug is pushed, the gums become inflamed and spongy, they bleed easily and the fetor becomes intense. With the gingivitis—inflammation of the gums—there is a glossitis and the tongue finally becomes so much swollen that the patient can hardly speak. Saliva is secreted in large quantities, particularly during sleep and the driveling often saturates the pillow. It is this symptom that gives the name ptyalism or salivation to mercurial poisoning which most frequently manifests itself as a stomatitis.

Patients are apt not to return for further treatment until their medicine is taken or their ointment is used up. I saw one case in which a patient neglected to report for observation till tremors had set in, indicating an involvement of nerve centers, and until the stomatitis had progressed so far that half the jaw-bone became necrotic and came away. Other things being equal, young persons will stand a great deal more mercury than older ones. Syphilis, on account of which mercury is is most frequently given, usually affords a tolerance of the drug, but this is not always the case, and the only safe plan is to watch each person to whom mercury is administered as if he were particularly susceptible to its effects.

One of the first remedies to be dispensed to a patient with ptyalism is a tooth-brush, a soft one, for the parts are exquisitely tender. An immense amount of offensive creamy exudate, which is itself irritating, will be found about the teeth. It is well to use a mild astringent and antiseptic wash for the mouth. Myrrh is commonly used. It is agreeable in odor and taste and it is moderately antiseptic and astringent. Advice should of course be given to discontinue the mercurial. Paradoxical as it may seem, there is a tendency to treat these cases with solutions of bichloride of mercury (1: 10,000) which are antiseptic and feebly astringent and which do not introduce an appreciable amount of mercury into the system. Personally I am not particularly impressed in favor of this treatment. In old times, when mercury was given more frequently and more lavishly than at present and when severe cases of ptyalism were much more common, potassium chlorate was used as a wash with good success, and I believe that the antiseptic element is important in the treatment.

Later on, in the period which this young man has reached, it is advisable to administer potassium iodide to remove the mercury from the system as a soluble double salt of potassium and mercury. This salt is eliminated largely in the saliva, so that if the iodide treatment were begun too early there would be an aggravation of the stomatitis. It sometimes happens that syphilitic patients show no indications of mercurialism under mercurial treatment but suddenly develop a stomatitis when iodide of potassium is commenced. Time is a great factor in the treatment of ptyalism. In another patient, who is still in the hospital, ptyalism appeared while mercury was being administered in double doses, internally and by inunction. He, however, had active manifestations of syphilis in the form of mucous patches and a mascular eruption—and I did not consider it advisable or necessary to interrupt the antisyphilitic treatment, more especially as the stomatitis was not severe. Accordingly he continued to receive the red iodide of mercury in doses of two milligrams, or one-thirtieth of a grain. A week or two of discontinuance from mecury will usually allow ptyalism to subside unless it has reached a high grade of inflammation. In the present instance I am not at all sure that there is syphilis to treat and, accordingly, the patient will be carefully observed after

the mouth symptoms have subsided, before returning to mercurials.

---

The next patient is a Swede, aged 33, married, and a tanner by occupation. He was admitted two weeks ago with this history. "Parents living and healthy, one brother healthy. Patient came to this country ten years ago. Has always been considered well till three weeks ago when he was taken with a chill followed by fever and a steady severe pain two inches above the umbilicus and to the right. Bowels constipated; feces whitish; appetite poor. On admission, tongue coated white with red streak in middle. Pulse 90, temperature 97°." The pain was not constant, but would come in paroxysms during which the man would writhe in bed though his courage kept him from crying out. Examination of the abdomen revealed little or nothing except that some one had punctured him at about the seat of the pain. Before he had been in the hospital twenty-four hours, he had a severe chill which shook the bed. His pulse went up to 130 immediately; the temperature was not taken because he could not keep still. On the next day he had another chill in which the pulse rose to 160 and then became imperceptible, while we succeeded in taking the temperature which was 104°. The patient threatened to die in collapse but he was revived by diffusible stimulants. We were on our metal to do all that was possible for him as he had told us that he had gone on for some time without relief and had come to us from Port Alleghany to be cured. On reëxamining him I determined that there was a slight bulging in the right epigastrium and hypochondrium. Upon percussion, his liver seemed enlarged and posteriorily I could detect quite a degree of tenderness. Pressure in front also elicited some complaint of pain. At this examination—which was made at eleven o'clock at night—the diagnosis of abscess of the liver was reached. The introduction of an aspirator needle suggested itself, but I reflected that if I made a puncture and struck pus, I was not prepared to operate and the withdrawal of the needle would infect healthy tissues. Even if the peritoneal surfaces had become agglutinated so that a septic peritonitis would not be set up, the wound of exit would be converted into a sinus. We waited accordingly till the next morning when I asked Dr. Park to make the exploratory puncture, indicating to him the point at which pus was expected, and requesting him to be ready to follow the puncture with a rapid evacuation of the abscess.

The patient was etherized and pus was found to a depth of $2\frac{1}{2}$ inches. It had the usual characteristic odor of pus from the vicinity of the intestine—such as is observed in ischio-rectal phlegmon. Once smelled, this odor is not forgotten. Some claim that the odor is due to the amœba coli. In cutting down on the liver it was found that the peritoneum had not become involved, that the liver was sliding up and down in front of the orifice with every respiration. In order to prevent infection of the peritoneum, the opening was made very large and iodoform gauze pushed into the aperture so as to make an antiseptic ring about the site of the intended puncture of the liver. Three or four pus-basins were filled with the contents of the abscess which was not like the usual discharge. This pus was gelatinous and transparent, whereas the pus of hepatic abscess is usually like tomato catsup, reddened with blood and darkened with disintegrated liver cells.

Relatively speaking, hepatic abscess is rare in this section of the world. In India, Mexico and other hot climates it is not uncommon, being due to the absorption of infectious material from the intestine. The starting point of the infection is a colitis, a dysentery without the ordinary conspicuous evidence of inflammation of the colon, being due to the amœba coli which does not cause the pain and the discharge of mucous and blood such as occur in other dysenteries. The resulting abscesses in the liver are usually large and single. Multiple hepatic abscesses usually develop in the course of pyæmia from infectious emboli. Sometimes traumatism is a cause of hepatic abscess. Not long ago I had a case occurring in a railroad man who was caught between two bumpers. The ulceration about gall-stones is another source of hepatic abscess. Rarely, there is absorption of septic matter from typhoid ulcers in the ilium or from typhlitic suppuration.

In the present case, I am rather inclined to think that the cause was a gall-stone, largely because no other cause can

be found. The favorable course of the case precludes the idea of pyæmia, the amœbæ have not been found and if the abscess were due to them we should expect a fatal termination. There is nothing in the history to point to typhoid fever inflammation about the cæcum or todirect injury to the liver. Gall-stones often exist through life without making their presence known till they are discovered at the autopsy. When, however, they serve as the exciting cause of a hepatic abscess, we expect some jaundice due to the plugging of a bile channel, whether the calculus is in the liver or in the gall-bladder or in the larger ducts. This symptom has been lacking in the present case.

Commonly, patients with hepatic abcess die; this man bids fair to be a favorable exception. The prognosis in pyaemic abscess is almost utterly hopeless. Even in the case of single abscesses, the cachexia produced by the septic absorption before the disease is recognized, commonly pulls the patient down so far as to preclude recovery. There was a group of symptoms in this case which at first made me hopeful that the trouble was less serious than it proved to be and which I wish to emphasize because it has often led to an erroneous diagnosis and postponed surgical treatment. The chill and fever occuring daily, the enlargement of the spleen and of the liver suggested malaria. But, when at the expiration of two days the condition was not relieved by the vigorous use of Warburgh's tincture, I waited no longer before urging Dr. Park to operate. The enlargment of the liver in these cases, which mimics intermittent or remittent fever, is due to a circumscribed collection of pus; the spleen is enlarged on account of the obstruction to the portal circulation in the liver; the chills and fever are due to the absorption of ptomaines. Too often, however, the differential diagnosis is not made till the autopsy is performed.

Aside from symptomatic and supporting medication, the treatment of hepatic abscess consists in operation. Even this in the case of pyaemic abscesses offers no hope, but in single abscesses an exploratory puncture should be made early and the abscess opened and drained if found. It is unwise to make an exploratory puncture unless the operation can be performed immediately, if necessary. I would, therefore, suggest that uniformly, the patient should be etherized and the instruments and dressings needed for the operation be laid out before the puncture, is made.

This patient was operated upon on the third day after admission to the hospital. It is now eleven days since the operation; he is still doing well and his recovery is confidently expected.

# COMMUNICATIONS.

## ON THE INCREASING PREVALENCE OF SCABIES.

HENRY W. STELWAGON, M. D., Philadelphia.

Under the same title, Dr. James C. White, several years ago called the attention of the profession to the increasing frequency of this disease, especially with reference to his own city, Boston.[1] This same tendency had been observed by me for the several years previously in Philadelphia, and had, indeed, been so striking that, at that very time, a great part of the data here presented was prepared for pub lication. Since then the proportion has kept its high place, and has, upon the whole, with slight fluctuation, been steadily growing, so that, at the present time, in the dispensary practice of this city, this disease constitutes ten to fifteen per cent. of all skin cases. The following table (Table I) summarizes my own observations at the various services for skin diseases with which I am or have been connected.

*Read before the Pennsylvania State Medical Society, 1893.

1The Boston *Medical and Surgical Journal*, February 14, 1889.

It will be clearly seen by a glance at this table that the itch is becoming a common disease among the poor, and that it is not limited to particular parts of the city, although it is, it is true, much more common at those centers toward which the foreign population trend. For example, the Northern Dispensary and the Jefferson College Hospital show the largest proportions, the former being close to the German population and the latter near the Italian and Russian Quarters. Moreover, it is not to be inferred that the percentages here given, although large, really represent the actual prevalence of the disease, for it is much more common than here noted—it is the custom in connection with dispensary services to record only such cases as personally present themselves, whereas, often enough, the patient is but one of a whole family affected.

Nor is this increase limited to one or two sections of our country, but it is widespread; naturally it is more frequently seen in our eastern seaport cities. This general prevalence is shown in the next table (Table II), made up from the returns of the various members of the American Dermatological Association as published in its Transactions:

Table II.* Showing the Increasing Prevalence of Scabies in Boston, New York, Baltimore, Chicago and St. Louis.

* Includes both dispensary and private cases.

When a disease of the character of scabies becomes so common among the poor, it may be certain that sooner or later it will, through many obvious channels, find its way among the better classes; and this is, indeed, already the fact. It was not until six or seven years ago that I saw a case in private practice, and then only one or two cases a year, whereas, now, an observation of ten to twenty cases is not unusual. This, I feel certain, is also the experience of my colleagues in Philadelphia and in other parts of the United States, as indeed the following table (Table III) compiled from the Transactions of the American Dermatological Association will show:

Table III.* Showing the Increasing Prevalence of Scabies in Private Practice throughout the United States.

| | 1880 | 1881 | 1882 | 1883 | 1884 | 1885 | 1886 | 1887 |
|---|---|---|---|---|---|---|---|---|
| No. Patients. | 2848 | 2641 | 3554 | 3656 | 2931 | 3737 | 2481 | 2849 |
| Scabies. | 15 | 7 | 26 | 34 | 33 | 49 | 56 | 62 |
| Percentage | 0.52 | 0.26 | 0.73 | 0 93 | 1.12 | 1.31 | 2.25 | 2.17 |

In seeking for causes for this increasing frequency, several of the more potential factors, which, according to my observation, are to a great extent responsible, should be referred to. Of first importance is the character of recent immigration. It is common knowledge that the average of the present immigrant is far lower in cleanliness, etc., than obtained some years ago, and this extremely undesirable class, largely made up of Russians, Poles, Huns and Italians, have, especially for the past eight or ten years, been arriving here in great numbers. Judging by dispensary observation it would seem that the itch is the normal state in the steerage of to-day, and many of those even who are free from the disease when embarking, are fairly certain to acquire it on their way over. These cases arriving in our midst are so many additional foci for its spread.

Another factor in its increase and not an unimportant one, is the "day nursery." An affected child is placed here for the day; it comes closely in contact with its comrades, and before its short sojourn is over, several more cases have had their origin and are themselves carriers for the further spread of the disease. The children's "home" and "asylum" are likewise often responsible, for it is not unusual to find that the invasion of a whole family may be traced to the return home of a child temporarily placed in such an institution. These statements are not made at random, but are based upon repeated observations. The cheap lodging houses are also fruitful centers of contagion; many of the Philadelphia (charity) Hospital cases have their origin in such places.

Another element in its increase, especially among the better classes, is to be found in the growing tendency to travel, and the rapid multiplication of traveling salesmen and drummers. With ordinary and proper precautions on the part of hotels this factor should sink into insignificance, but it is extremely doubtful if the linen in the average hotel is always changed or changed in its entirety after a single night's occupation, and yet, if not, and had an affected person slept therein, the next occupant will almost assuredly contract the disease. I mention this method of spread for the reason that in a large proportion of private patients whom I have treated for scabies, the disease could be distinctly traced to such a source; nor were the cheaper hotels alone culpable. Finally the failure on the part of physicians to recognize the disease, especially when ill-developed or in its beginning stages, must be looked upon as an important element in explaining its increasing prevalence. This is not said to reflect upon the profession, for it is the result of lack of opportunities. Graduates of the present day, if they make use of their advantages, are pretty well schooled in the recognition of this disease. As it is now a common one at the clinic; but some years ago, during my own student days in fact, the presentation of a scabies case was rare.

There are several points regarding the eruption which if kept in mind, will serve to prevent error in diagnosis—distribution, itchiness, multiformity, the presence of burrows (cuniculi) and the linear character of many of the lesions; inquiry will, moreover, in a majority of the cases, disclose the existence of the disease in a bedfellow, comrade, or in others of the family. The burrow, which is pathognomonic, is not always present. Special stress, in my opinion, should be laid upon the distribu-

* After 1887, the private and dispensary cases were merged in the returns. Since that date, private cases have, according to my own experience and that of others, increased almost as rapidly, unfortunately, as have dispensary cases.

tion and the linear character of the lesions as diagnostic symptoms of great value and invariably present. Some or many of the lesions are always found to be longer than they are broad, appearing as elongated or oblong papulles, vesicles and pustules; scattered lesions of this kind, especially when seen about the fingers and hands, wrists, axillary folds, shaft of the penis, and anal region, even though few in number, should always excite suspicion. As a rule, private cases are most difficult to recognize, inasmuch as such persons are usually extremely solicitous about any skin irritation, take daily baths, use soap and water freely, so that the disease is measureably held in check and the eruption remains scanty. It is not rare in some of the private cases to find but two or three lesions upon the fingers or other parts of the hand, possibly a few on the wrists, one or several on the penis with here and there an excoriated papule or a scratch mark over the lower trunk. Even in private cases the anal region is a common site for several or more lesions.

The treatment is well-known. It is as simple as it is efficacious, and every case thoroughly and quickly cured frees the community of a moving and active contagion. In the average case of the dispensary class, I have usually prescribed a compound ointment, consisting of an ounce of sublimed sulphur, an ounce of Peruvian balsam, thirty to sixty grains of beta- naphthol, and sufficient benzoated lard or petroleum ointment to make up four ounces. The patient is directed to take a soap and hot water bath; ordinarily any good toilet soap will answer, but in those of sluggish, thick skin, or of filthy habit, a good sulphur soap or sapo viridis is preferable. After the bath the ointment is to be energetically rubbed in over the whole surface from the chin down, special attention given to the parts most affected. The back should not be neglected, the application to this part being preferably made by another person. Clean linen is put on and clean bed linen used—the soiled linen is to be boiled. At the end of ten or twelve hours another application of the ointment is made, and so on for six applications. During this time the same linen is worn. Some hours or a half day after the last application, another bath is taken and a complete change of linen made. The linen which had been worn, as, in fact, all the underwear and bed-linen before being used again, should be thoroughly boiled. By boiling, all stray parasites and their ova are destroyed.

During the treatment it is advisable to have a dusting powder of sulphur sprinkled in the bed, in the bureau drawers, and in other suspicious places. All outer clothing should be subjected to high temperature if possible, or thoroughly beaten and hung out in the air and sun. Other members of the family should undergo inspection, those affected should be treated as above, and those doubtful advised to make two or three thorough applications. It is only in this manner that the disease is cured and recurrence prevented. In young children and infants the beta-naphthol is omitted in the above ointment and the quantity of sulphur reduced one-half. In these younger cases, particularly infants, the disease often invades both face and scalp also, especially the lower part of the former, and this fact should not be forgotten in the treatment. In private practice I have commonly prescribed the same ointment, with beta-naphthol omitted; in some cases also an ointment of equal parts of styrax and lard; two to four applications will usually suffice in these patients.

To control the cutaneous irritation which is not infrequently set up by the disease or by the sulphur applications and which sometimes persists for several days or longer after active treatment has been discontinued, it is well to advise the application, two or three times daily, of a saturated solution of boric acid containing one to three drachms of carbolic acid, two drachms of glycerin and four drachms of alcohol to the pint. Should the treatment have been inefficiently or carelessly carried out, as not infrequently happens in dispensary practice, evidences of an active return of the disease will soon appear, and a repetition of the plan described above, somewhat abbreviated, will be found necessary.

As to controlling the spread of the disease in the broad sense of the term, and placing it again low down among the comparatively rare skin diseases, I am convinced much can be done. The recognition and prompt cure of each case as soon as it is presented, as already remarked, is a step in the right direction; patients should be cautioned as to the contagious

nature of the disease. Moreover, there is absolutely no reason why an immigrant with the itch should be allowed to land; the disease may be rapidly cured when circumstances demand it by employing much more energetic measures than those already mentioned, but which need not be outlined here. Such an immigrant may be rendered entirely harmless in an hour or so by vigorous treatment, during which time his clothing and effects could be baked, steamed, or sulphur-fumigated. Energetic treatment of this kind, it is true, leaves the skin in a state of active irritation, but this, with several days' use of a mild soothing ointment, will subside. Infants and young children should be carefully inspected before being admitted to "day nurseries," "asylums" or "homes," and if found with any evidence of skin disease, should be rejected till a professional assurance of its harmless character is obtained; the same rule should be applied in the admission of children to the public schools. Hotels, small, or large, should be legally required to make a complete change of bed-linen before the bed is assigned to another occupant—to say nothing of why this should be done for many other reasons. Lodging-houses, to which cases may be clearly traced, should be reported to the Health Board for investigation and for the institution of proper measures for disinfection.

It is, I know, a common thing to speak of the itch with more or less humor, as a joke, but it is an exceedingly unpleasant experience for the immediate victim, his family, and the community at large. A disease so readily cured, so readily controlled, and so readily preventable as this, has no reason for its existence in our midst, certainly not to such a great extent as it exists at the present day.

## ABDOMINAL SURGERY BY UNTRAINED OPERATORS, WITH DEFICIENT APPLIANCES.

J. McFADDEN GASTON, M. D., Atlanta Ga.

The discussion going on recently in regard to the recognition of emergency work in surgery indicates that while the higher types of operative procedures should always have precedence, there is a place for that class of measures called for at times by the necessities of the case. Of course, no one unqualified for surgical work or without the means of executing it properly, should undertake the management of a case when a surgeon of experience can be secured to do it. But the question is raised, whether in the absence of an expert operator, any member of the profession who is called to see a patient suffering from recent traumatism should feel authorized to meet this exigency with promptness by a life-saving operation when delay would prove fatal. If it were a case of hemorrhage from the division of an artery, though temporary compression would arrest the bleeding for the time, it could not avail for permanent relief, and ligation of the vessel should be resorted to even by the most inexperienced practitioner, without the ordinary appliances for such an operation.

But the class of cases which has elicited this discussion is of a different nature, and there may be degrees of urgency, in all of which interference is not imperative, and in regard to which it is questionable whether an untrained operator would be warranted in proceeding. This issue is made now especially in regard to penetrating wounds of the abdomen and thorax. Should there be a protrusion of the abdominal viscera from an incised wound of the parietes, and it was found that the coats of the intestine were cut or that a mesenterie artery was divided, it is evident that there should be no hesitation on the part of the medical practitioner, least qualified for surgical work, about proceeding to suture the opening and ligate the vessel, without waiting for a specialist. But in the event of perforation without protrusion, a grave question arises in the diagnosis and scarcely less grave in the results of cases left alone, are those which have undergone laparotomy. It is not generally taken into account that the facts as recorded, show a larger mortality from the cases of abdominal injury which have

been operated upon, than from those treated without operation. I drew attention to this matter in the discussion of Dr. Link's paper before the surgical section of the American Medical Association at Milwaukee, and the inferences may be drawn, that if the percentage of mortality has been increased by laparotomy in the hands of skilful operators, we should not expect better results from unskillful use of the knife and the needle. It would seem, therefore, unwise to encourage the laying open of the abdomen by medical men without surgical experience in this class of cases. It is preferable to leave a patient with an abdominal injury, that may or may not suffer from a visceral lesion, to be treated without operation, to having an operation performed without all due precaution in the steps taken from beginning to end. The great practical deduction to be made from a consideration of this subject is that abdominal surgery should receive the most careful attention of those who expect to undertake the treatment of visceral injuries, and in view of the mortality which has attended laparotomy in this class of cases, it is not expedient that those without skill and experience should be encouraged to open the abdomen.

## CLINICAL ASPECTS OF PNEUMONIA IN CHILDREN.*

HENRY E. TULEY, M. D., Louisville, Ky.†

Clinically and pathologically, we divide pneumonia into a fibrinous, croupous or lobar type, and a catarrhal, lobular or broncho-pneumonia. There is also an interstitial variety which is rarely seen and upon which I shall not dwell.

I use the terms "lobar" and "broncho" when speaking of the divisions, as they to my mind more clearly define the condition present.

Oftentimes, clinically, one is unable to differentiate these forms, and even macroscopically at the autopsy, we are unable to distinguish a broncho-pneumonia from a generalized croupous pneumonia; so it remains for them to be classified for us by the pathologist.

The differences pathologically I will not mention, but will endeavor to point out wherein a diagnosis may be made from a clinical standpoint alone.

*Lobar Pneumonia*: This form is generally primary; its onset sudden, ushered in by a chill or a slight chilliness, perhaps by a convulsion or convulsive twitchings; there is generally languor, headache, and an initial temperature above 101°; there may be vomiting with or without diarrhœa.

The appearance of the child is suggestive; there is pallor, an anxious, pinched expression, the face drawn, the alæ nase active, the respiration hurried.

Frequently its onset resembles very much that of scarlatina, but upon the non-appearance of the rash, pneumonia should be suspected and a careful examination of the lungs be made.

As to the method of examination; care should be taken not to expose the little patient more than is absolutely necessary. It should lie either upon the lap or shoulder of mother or attendant, the endeavor being made to distract attention from the minutæ of the preparations. It is my opinion that a thorough auscultatory examination of the chest cannot be made without the aid of the stethoscope. With it we are able to localize a small area of pneumonia. We can auscultate high up in the axilla or in the clavicular regions—favorite sites for consolidations—which in a thin or emaciated infant would be impossible with the ear alone. I use the binaural stethoscope with the concealed spring by which the pressure in the ears can be regulated and will remain constant—an end which we are unable to accomplish with the rubber band generally used.

*Physical signs* : These may be present at the initial examination, but they are oftentimes delayed until the third or fourth day, and indeed there may never be present the typical signs of a consolidation.

Upon auscultation, if seen early and signs are not delayed, we may expect to find at first evidences of a more or less consolidated lung, distant or weak vesicu-

* Read before the Falls City Medical Society, July 13th, 1893; and by title before the Mitchell District Medical Society.

† Clinical Assistant to the Chairs of Diseases of Children and Practice of Medicine, Kentucky School of Medicine.

lar breathing, or if the consolidation is near the surface pure bronchial breathing more or less distinct. Care should be taken not to mistake the exaggerated compensatory breathing heard over the opposite lung or normal part of the affected lung, for bronchial breathing which it oftentimes simulates very closely. Pleuritic friction sounds or loose mucous râles are heard over the affected area; the former "we may expect to find when there is a large area of consolidation present." *

The *Pneumonic sigh,* which is present in the large majority of cases caused by the short sharp expiration, is a valuable aid oftentimes in eliciting broncophony, or the increased voice sounds, over the consolidated area.

By the child's crying we gain the same ends, and by palpation often, through the thin chest walls obtain vocal fremitus.

Percussion is the least reliable means of diagnosis. There may be marked dullness approaching flatness, slight dullness, or merely a slight modification of the normal pulmonary resonance, or as is most often the case, no change at all perceptable in the percussion note over the consolidated area from that obtained over normal pulmonary tissue.

This fact may be caused by the area of consolidation being superficial, normal resonance being transmitted from sound tissue beneath, or a (perverted) sound may be produced by a distended stomach pressing upon and displacing the lungs.

When dullness or modified pulmonary resonance are present, they are valuable aids in the diagnosis.

The character of the sputum is of no assistance in making a diagnosis as it is rarely seen in a child, being swallowed as soon as dislodged.

The *temperature*: As before mentioned this usually at the onset is above 101°—often 104° or 105°—its course is varied. It may be continuously high, irregular or remittent; in the latter form normal is rarely reached. Most frequently the temperature in lobar pneumonia ends by crisis, especially is this so in children over three years of age; and the most critical days are between the sixth and the eighth, the temperature at this time may fall to an unusually low point, so much as 8° or 10°, frequently reaching 94° or 95°.

A post-crisis rise often occurs, the temperature rising a degree or two following the crisis, reaching normal the next day. If this rise is prolonged we may suspect a complication, either the extension of the process into new areas of the lung or a pleurisy or an empyema.

*Broncho-pneumonia:* In the majority of cases this form of pneumonia is secondary to a bronchitis, or occurs co-incidently with, or as a sequela to, the exanthemata —or to pertussis or other wasting diseases.

If bronchitis precedes an attack we have an aggravation of the symptoms present. Respiration becomes more hurried, dyspnœa often marked, the temperature rises as a rule; in short the symptoms already present are exaggerated. There may be present bronchial breathing, but it is more frequently absent, our diagnosis being largely made up then "from the severity of all the general symptoms, cough, prostration, restlessness, dyspnœa, and cyanosis.*

The temperature in broncho-pneumonia is variable, no typical course being followed. In the majority of cases it is high and remittent, in others it is 103° or below, but it is not infrequent that we have a temperature running below 101°, sometimes even subnormal; the latter occurring more frequently in children who are delicate than among those of robust condition.

There is generally an evening exacerbation but it is not unusual to meet with the opposite condition, a higher morning temperature, lasting for several days. The subsidence of the temperature in this variety is by lysis. The duration very varied, cases being reported where it has lasted fifty-one days.

As to physical signs—the absence of both dullness and bronchial breathing does not by any means preclude the presence of pneumonia, for the patches of consolidation may be so disseminated with normal pulmonary tissue intermixed, as to cause no deviation from the normal pulmonary resonance or change in the respiratory note, except perhaps a slight weakening of the latter. The presence and the character of the râles and particularly their location is of importance. Finding a localized area of râles either on one or

* Holt Archives Pediatrics.

*Holt.

both sides should cause pneumonia to be suspected, especially if over one or both lower lobes behind.

*Complications:* In both forms of pneumonia the appearance of a complication is serious. Pleurisy more or less severe is generally present with pneumonia, but an extensive inflammation of the pleura with or without exudation or an empyema either of which may be associated with pneumonia, greatly retard convalescence and resolution.

A co-incident inflammation of other organs may occur—of the kidney or pericardium; jaundice is often seen and diphtheria may develop. Meningitis is frequently met with as a complication principally in the lobar type, but I think it a mistake as is the wont of some authors to give to the location of the consolidation a causal relation to the meningitis. It has been said that when the apex is involved, meningitis, convulsions and other nervous symptoms are particularly liable to occur, but my post-mortem experience has shown them to have occurred with as great frequency when the consolidation was located elsewhere.

A chronic pneumonia, or caseation may be the result of a broncho-pneumonia and enlarged, suppurating and caseous bronchial glands are often found following this variety.

The *prognosis* in uncomplicated cases of lobar pneumonia is good, the mortality being only about 2 per cent.; that of broncho pneumonia has been variously stated. Holt gives it in 161 cases at 64 per cent.

The *diagnosis* in most cases is not difficult, though there are cases of broncho-pneumonia which simulate very much the lobar type, and which from first to last are open to doubt. The sudden onset of the lobar variety, not following any other disease, the rapid development and clear limitation of the pathognomonic signs, the crisis in the temperature, and the rapid resolution decide us in this type. Contrast the slow development of a broncho-pneumonia, perhaps following a bronchitis, or occurring during a summer diarrhœa, the irregular temperature and its slow fall, the ill-defined signs and delayed resolutions.

In conclusion a word in regard to the improper use of the term "capillary bronchitis" so prevalent among medical writers and statisticians. It is impossible for an inflammation of the bronchi to occur in an infant without the morbid process extending to and involving the surrounding structures, and I believe that such are all clinically and pathologically cases of broncho-pneumonia and not "capillary bronchitis."

## WHOOPING-COUGH IN AN INFANT EIGHTEEN DAYS OLD.

JOHN M. CURRIER, Newport, Vermont.

On the 25th of June, 1893, I was called to see a child, eighteen days old, said to be suffering from whooping-cough. I found a family of seven children, three of whom were coughing characteristically with whooping-cough. Two had been coughing for about three weeks, and one other, I afterwards learned, came down in a few days. The babe I was called to see, was having paroxysms of strangling or coughing, at intervals of three or four hours, accompanied by asphyxia. Between these paroxysms the child lay comatose, without inclination to nurse, and when an attempt to feed it was made a paroxysm of choking would occur, accompanied with cough. These symptoms had been increasing for three or four days. My prognosis was unfavorable. The child died the following day in a paroxysm. There were unmistakable symptoms of the disease for fully one week previous to its death.

Did the mother receive the poison in her system before the birth of the child, and communicate the disease through the blood to the fœtus? Some of the older children had had the disease years previously, but were now coughing, undoubtedly from inhalation of the atmosphere contaminated by those having the disease. The mother had some slight persistent cough similar to the others, but without the whooping. This case was the youngest subject I ever saw affected with the disease; but there was not the slightest doubt about the character of the trouble.

# A TREATMENT FOR FISTULA IN ANO WITHOUT A CUTTING OPERATION.*

T. J. BENNETT, M. D., Ausitn, Texas.

At the San Antonio meeting of the Texas State Medical Association, held in April, 1889, I presented to that body a short paper with the above title, in which I endeavored to explain a very simple procedure for the relief of fistula in ano, basing the claim for the treatment upon the report of five or six well selected successful cases.

The operation consists in first thoroughly cleansing the lower bowel and the fistulous tracts with an antiseptic wash, by means of a suitable syringe. I use for the sinuses a long-nozzled uterine syringe, capable of considerable force, and a twenty-five per cent. solution of peroxide of hydrogen, or a simple carbolized solution, with which the tracts are freely flooded. The next step is to thoroughly divulse the sphincter muscle in the usual way with the fingers. Then again irrigate the sinuses in the same careful manner as before with the same solution, and last with plain water. After this, inject into the tracts a solution of nitrate of silver, forty to sixty grains to the ounce of water. Then with a little carbolized oil, or vaseline, spread upon absorbent cotton and bound to the parts with a bandage, the operation is completed in simple cases.

In cases of the internal blind variety of fistula, openings should be made from the outside with the knife, in order that the pouches which are always formed at the termini of such tracts, and which always contain pus and debris, may be washed out and the sinuses cleansed. The only cutting necessary is in this variety, and possibly the enlargment of some of the external openings for the nozzle of the syringe which is introduced only far enough to inject the fluid. With an experience so limited as mine has been, it would be presumptuous in me to claim to have discovered a treatment that would supercede the long tried and successful methods of our text-books. I can only say that the above treatment is simple, and so far as I have tried it, it has been successful in every instance. Even a case of recto-vaginal fistula operated on in the same manner, recovered in a few days. In this case I may say that I employed a six or seven per cent. solution of carbolic acid, instead of the silver, because I did not have the latter solution with me, not knowing or thinking that I should be called upon to do more than lance an abscess, as I had done before for this patient on two occasions within a year.

The time saved to the patient in this operation constitutes one of its chief advantages. The number of days required to remain in the recumbent position is from four to eight, and with no wounds to dress and keep clean, the patient spends this time in comparative comfort.

I wish it understood that I do not claim anything original in this operation, except, possibly, that I have placed together in an unusual manner, some well known methods and principles.

The necessity of thoroughly cleansing the sinuses, getting rid of all foreign particles and matter, has been recognized and appreciated from almost the beginning of time. Also the divulsion of the sphincter has been employed, and some good results have been reported from this alone. And too, the injecting of irritants into fistulous tracts has been resorted to, and reports have been made of cures resulting from this alone.

But the arranging of these things in the manner and order given belongs to me so far as I know. The rationale of this treatment is based upon some well established surgical principles, together with a reasonable appreciation of the anatomy, pathology and physiology of the parts involved. In the first place we have to deal with the most dependent portion of a long and tortuous tube, the blood supply of which is influenced by gravitation, and whose return flow is through veins that are without valves and against gravity; with a mucous membrane that is in a constant state of hyperemia existing in all persons, it is claimed, whether they have ever had rectal disease or not. And further, we have a large ring-shaped muscle, the sphincter, which has scarcely

*Read before the Austin District Medical Society. 1893.

any bony attachments, and whose fibers are closely adherent to the integument, and blended more or less intimately with the other muscles and structures about the anus. This muscle stands vigilant guard over the great outlet of the human body. It is quite easy, then, to understand that the sphincter is very important, and that it is liable to become wonderfully hypertrophied from inflammatory stimulus during disease of these parts. The longer the disease continues, whether hemorrhoids, fissures or fistulæ, the greater the amount of blood to the parts, and consequently the larger the muscle grows and the stronger it becomes. Thus with increased size and strength there is a corresponding retardation of the return circulation which favors disease, and above all, there is a wonderful increase in the muscular tension of the whole ano-gluteal region. The voluntary power of this muscle is diminished and the involuntary power is proportionately increased, which also favors disease. Now, a fistulous tract, it matters not what produces it—a foreign body that has lodged above the sphincter, a traumatism, constipation, or what not, anything, in fact, that would cause an abscess,—for an abscess under all circumstances, it is claimed, causes the sinus—this fistula, except in the superficial form, has its origin above the sphincter within the bowel, and extends more or less tortuously down by the side of, and exterior to the muscle, and makes its exit through the skin within an inch or two of the anus. Let there be many of them or only a few, the destructive process is the same in all. The high tension of the muscular tissue causes retraction of the severed fibres, in accordance with the only function of muscular tissue, viz., contraction, and the result is non-coaptated walls. It may be likened to a taut suspender. As the rubber threads are cut they retract, leaving an elliptical or round-shaped hole. So in the case of the fistula in ano. Fecal matter, when in a liquid state, is always present in these sinuses, and prevents, together with the abnormal tension of the parts, a union by any plan of treatment other than cleansing and relaxing the tension. This removes the debris and permits the coaptation of the walls. The nitrate of silver is used simply to hasten union, which it does by exciting a temporary inflammation along the tracts, thereby causing a cure before the paralyzed sphincter can regain itself. This is exactly what is done when all of the holes are cut into one, the standard operation for this trouble. The sphincter is severed, which relaxes the surrounding parts and permits the cleansing of the tracts and the coaptation of the walls. Now, it is proposed to do no more than to state what has been the results of my limited experience with the operation which I have had the honor to present to you to-day, and I may be permitted to summarize the advantages claimed as follows:

1. There is from one week to a month saved in time to the patient.
2. There is less danger from incontinence.
3. There is no danger from embolism.
4. There is no suppurating wound to require daily dressing and cleansing.
5. The operation is practically robbed of its terrors.

Certainly, then, the operation is simple, and to my mind reasonable, and therefore I respectfully commend it to your further investigation and trial.

---

### Japanese Double-tailed Fish.

The writer of "Science Notes" in the *Daily Chronicle* has a most interesting paragraph on the way in which the Japnese produce their extraordinary breeds of double-headed and double-tailed fishes. He quotes Dr. Ryder's conclusion that these ingenious people shake or disturb in some way the eggs of the normal species of gold-fish, and so interfere with the natural development of the organism. In confirmation of this theory he adduces the fact that Professor Weber, by actual experiment with the ova of common pike, produces double monstrosities of this kind "when the recently fertilized eggs were violently shaken." It is not improbable that the artificially-produced peculiarity of the double-tail might be inherited and become fixed. "We know that even in the higher animals monstrosities are often inherited, though the higher we advance in development the less apt are monstrosities to appear. We often see a two-headed calf, but the Siamese twins are phenomenal."

Tolled her love—The wedding bells.

# SUTURING THE TENDO-ACHILLIS IN THE CORRECTION OF DEFORMITIES OF THE FEET.*

H. AUGUSTUS WILSON, M. D.†

Experience has shown that in most of the deformities of the feet, that require operative procedures for their correction, the tendo-achillis demands section, and not infrequently the lengthening or shortening of that structure only is required.

It is clearly apparent that all remedial measures, to be ultimately and progressively efficient, must have for their object not alone removing the appearance of the deformity by lengthening or shortening of tendons, but it is equally essential that the resulting strength of the tendon must be equal to the demands to be placed upon it.

The tendo-achillis communicates to the heel the power required to enable the arch of the foot to maintain the weight of about three times as many pounds as it exerts pounds of force. The leverage of the foot, in walking, is that of the second order of levers, that is, where the weight is placed between the power and fulcrum, the power being applied to the posterior end of the os calcis, the fulcrum being the distal extremities of the metatarsal bones, while the weight is imposed upon the astragalus.

Careful measurements of over a hundred approximately normal feet have resulted in showing that the average comparative distance from the end of the os calcis to the center of the internal malleolus, and from that point to the end of the distal extremities of metatarsal bone of the big toe was as 1 to 3.

This adverse position of the weight in its relation to the power and fulcrum, necessiates the use of a greater power moving through a small distance, to lift weight equal to one-third of the power through a proportionally greater distance.

The powerful action of the gastrocnemius and soleus muscles would be less confusing if it could be disassociated from its attachment to the weight it is to lift. Let it therefore be assumed that the upper end or insertion of this muscle is made fast to some immovable body and then its action in lifting the whole body will be apparent. A force of one unit, applied to the power end of this lever, would raise a weight of three units, if the foot was reversed, that is if the tendo-achillis was attached to the tarso metatarsal joints. This is the most common application of the second order of levers because it enables a small number of pounds of force to move a larger number of pounds of weight in proportion to its distance from the power and its approximation to the fulcrum. The advantages of less power is, however, at the expense of the arc of movement of the power end of the lever. Economy of space even at the expenditure of increased power often becomes necessary in the arts and is well exemplified in the human foot.

This expenditure of power, equal to three times the weight to be moved, requires that the means of communicating the power should be equal to the maximum strain that might be required to sustain additional weights, and thus we perceive that the tendo-achillis is the most important and, at the same time, the strongest and broadest tendon in the body.

The great importance of the tendo-achillis in locomotion, as indicated by its breadth and strength as well as by its mechanical function, demands that its strength and general utility after operation should be increased rather than lessened, and that the correction of the external appearance of a deformity should be secondary to a full re-establishment of the mechanical functions of the part.

The subcutaneous operation for lengthening the tendo-achillis, while it has had a brilliant career in assisting in the correction of deformities of the feet that were previous to its adoption corrected in part only, did not always fully meet the requirements.

The gaps between the divided ends of the tendons were filled by ultimate fibrous union which yielded when there was full contractile power in the gastrocnemius and soleus muscles, and only failed to yield

*Read before Pennsylvania State Medical Society, 1893.

†Professor of General and Orthopedic Surgery in the Philadelphia Polyclinic, Clinical Professor of Orthopedic Surgery in the Jefferson Medical College and the Woman's Medical College.

when those muscles were largely inactive from previous disuse.

The disturbance of the repose essential to a perfectly solid union was clearly shown by a patient upon whom I spliced the tendo-achillis under the local anæsthesia of cocaine, the contractions of the muscles increased the separation of the ends, a full inch, and this constant or voluntary contraction must make the uniting band attenuated.

It is impossible to disassociate the shrunken, atrophied, and often, useless calf with the possibility of its being assisted in its retrograde, by the weakened condition of the tendo-achillis divided in the often hap-hazard subtutaneous method.

If there was, prior to divison of the tendon, an atrophy or enfeebled calf, analogy would indicate that favorable condition would promote its growth and development until a full or approximately full usefulness could be obtained.

That the new band of union uniting the tendon is capable of stretching has become will established in cases that have required open section at some subsequent time. Several illustrations of this have come under my notice, in one of which the originial separation of one inch had increased to two and one-fourth inches. The fibrous connecting band was extremely thin and so firmly bound to all the surrounding structures that a most careful dissection was required to lift it from its bed. It wasfound to be attenuated to suchan extent that it was found impossible to use it in the effort to shorten the tendon, and recourse was had to a method of splicing, by taking parts of the original tendon.

In a large number of relapse cases that have required subsequent division of the tendo-achillis, it has been found that it was practically impossible to find a tendon. The extensive amount of elongation so often seen after transverse fracture of the patella is still further evidence in the same direction.

The inaccuracy and, therefore, uncertainty of the results to be obtained by simple subcutaneous division of tendons made the reception of methods of accurately elongating and shortening tendons, by splicing, a boom that has been rapidly seized by progressive operators. Although asepsis prepared the way, surgeons were not ready to take the advanced step of suturing tendons until time had elapsed to prove the benefits to be derived from the simple section through an open wound.

I desire to here acknowlehge my personal indebtedness to Dr. W. W. Keen, of Philadelphia, from whom I first learned, on March 4th, 1891, of the practical application of accurately lengthening tendons. On the above date Dr. Keen read before the College of Physicians of Philadelphia, a paper entitled: "A New Method of Tenotomy, by which the Tendons are Lengthened to a Definite Extent, instead of the present Hap-Hazard Method."

The patient, with post hemiplegic contracture of the flexors of the fingers, was operated upon by Dr. Keen, on November 29th, 1890. The method of procedure was then described. "Each tendon was first split in the middle, one and a quarter inches, and then, at the two ends of this incision, section of the opposite halves of the tendon was made. The two cut ends were then slid past each other and sewed together for a distance of half an inch, making three quarters of an inch of lengthening." On December 19th, 20 days after the operation, it is recorded "She went home to-day. Her hand is in much better condition though she cannot yet flex the fingers to any extent. The tendons are not torn loose, in as much as extension faradization flexes the fingers."

Quite recently, March 25th, 1893, the *Centralbatt fur Chirurgie*, published an article by Dr. Trnka entitled "A Contribution to the Technique of Suturing Tendons" in which the author speaks of methods which he employed for the first time in 1887. Trnka utilizes a lateral section of the upper portion of the divided tendon which he turns down and stitches securely to the lower portion, or else he unites the divided ends by strands of catgut securely sutured to each of the divided ends of the tendon.

While the two methods of acurately operating upon tendons were devised for the purpose of elongation, that which is most frequently required, I was impressed with the applicability of the longitudinal splicing method to the shortening of tendons.

In the discussion which followed the reading of Dr. Keen's paper on March

4th, 1891, I spoke of its applicability to shortening tendons. On June 10th, 1891, I resorted to the method in a case of paralytic talipes calcaneus, and have since that had occasion to employ it four times, although there are no published records.

Other surgeons embrace the methods described and, in addition, those in which it was attempted to obtain the same result by recourse to subcutaneous methods. It is clearly apparent that the essential feature of the methods described is the suturing together of the splice so that the elongation or shortening should be of a definite amount. In the subcutaneous methods there has been no attempt as far as I known to suture tendons, and shortening cannot be accomplished subcutaneously.

## LARGE CYST OF KIDNEY; NEPHR ECTOMY; RECOVERY.*

L. S. M'MURTRY, M. D.†

The extension of the field of abdominal and pelvic surgery, and the splendid results attained in recent years, have become so familiar to the profession that isolated cases have ceased to be of special interest. The following case, however, is somewhat unique, and illustrate so many important practical points that I deem it worthy of special report and discussion.

On June 26th I was asked by my friend, Dr. Henry E. Pelle, to see a patient with him in the west end of the city. The patient is thirty-two years of age and unmarried, and presented the following history and symptoms: About three years ago she noticed an enlargement of the abdomen toward the left side. It gave her no discomfort at first, but she observed that it steadily increased in size. During the past year it had grown rapidly, and had now assumed the proportions of a large abdominal tumor, giving her abdomen the general contour and appearance of a woman far advanced in utero-gestation, except the tumor was larger toward the left side. Her general health was excellent, except that she was losing flesh, and suffering more and more with pressure symptoms. During the past few months she had preceptibly emaciated, and was unable to eat a full meal on account of the discomfort following. Her activity was interfered with also, being unable to discharge her duties easily on account of the weight and pressure of the tumor. Physical examination of the abdomen disclosed the typical signs of a monocystic ovarian tumor. It occupied the general abdominal cavity as well as the pelvis, had pushed the uterus backward into Douglas' space, thinned the abdominal walls, and fluctuated distinctly upon percussion. All the symptoms were characteristic of a cyst. Abdominal dropsy was readily excluded. She had expressed her desire to Dr. Pelle for permanent relief, and he had made known to her the necessities for operative interference. She was at once placed upon preparatory treatment, and went to the infirmary to undergo the operation.

The operation was performed on July 3d, at 9 A. M. Besides assistants and nurses, Dr. Pelle and Dr. R. C. Chenault, of this city, were present. A free incision was made in the median line between umbilicus and pubes, as in ovariotomy. On dividing the parietal peritoneum I was puzzled by finding another movable layer of peritoneum covering the cyst. My first thought was that it might be an ovarian cyst which had grown in the leaflets of the broad ligament so as to present such a duplicate fold of the serous membrane, but passing my two fingers down in front of the cyst into the pelvis I found both ovaries in their proper position, and quite normal in every respect. This demonstrated that the tumor had its origin in the post-peritoneal space, and had carried the peritoneum in front of it in its development. Following the outline of the tumor with my hand, I soon traced its attachments to they left lumbar region and satisfied myself that I was dealing with a large cyst of the left kidney. Announcing this to the anæsthetist, Dr. J. W. Guest, he immediately substituted

* Read before the Clinical Society of Louisville, July, 1893.

† Professor of Gynecology in the Hospital College of Medicine, of Louisville.

chloroform for ether, which he had been using up to this stage of the operation, and continued to use chloroform throughout the remainder of the operation. Cystic degeneration of the kidney usually presents a large number of small cysts clustered together, and hydro-nephrosis, which is the result of an obstructed ureter, is limited for the most part to the pelvis of the kidney with varying degrees of renal structures preserved. This cyst, however, presented the pearly hue of an ovarian cyst, and, as the specimen presented herewith shows, consists of the capsule converted into a large single cyst. The capsule was distended and rendered very thin. It was easily punctured with the trocar, and the contents emptied into the tub beneath the table. I presume that it contained about one gallon of clear serous fluid. After emptying the cyst I found quite a task presented in separating the sac from its attachments to the peritoneum of the left lumbar region, and in freeing it from the spleen, to which it was firmly attached, and which appeared as a cap to the tumor.

In separating the spleen, although observing the utmost care, I injured the capsule of that organ and denuded a considerable surface upon its inferior border. This started a capillary hemorrhage, which persisted throughout the remainder of the operation and for three days afterward. After freeing the cyst in all directions, I tied the ureter and divided it. I then secured the renal vessels with a strong silk ligature, ligating them in two parts, and cut away the cyst. I then closed with fine silk sutures the opening in the posterior layer of the peritoneum, through which I had delivered and removed the diseased kidney. An examination of the kidney on the right side at this stage of the operation demonstrated that it was of normal consistency, but very appreciably enlarged, which I attribute to the additional work thrown upon it by the progressive crippled condition of the other kidney. After cleaning the abdomen thoroughly and securing all bleeding points, I found the denuded surface of the spleen still oozing, and that the sponge packing I had applied had done little to arrest it. The bleeding was not great and not active, but consisted of a steady oozing of bright blood.

In order to deal with the pedicle and secure thoroughly the renal vessels, I had made a transverse incision in the abdominal parietes at right angles to the median incision, and extended this into the left lumbar region. I now closed the abdomen by suturing carefully both incisions, being careful to adjust accurately the severed rectus muscle end to end, and having placed a glass drainage-tube through the lower angle of the median incision, with the point resting in Douglas' space, where all oozing fluid would naturally gravitate, the usual dressing was applied, and the patient put to bed in good condition. There was no sweating or other symptom of shock, the pulse being 104 and of good volume.

The convalescence has been exceptionally easy and uneventful. The secretion of urine was quite free, and indicative of excellent kidney function. This has continued without interruption throughout her convalescence, and as it is evident from the specimen that all secretory tissue had long been destroyed in the diseased kidney, its fellow had evidently assumed compensatory structural and functional activity. The drainage was quite free for the first twenty-four hours, the bright color of the blood showing that it came from the spleen. This gradually ceased, and the tube was removed on the fourth day. The pulse remained under 100, and the highest temperature recorded was 99.6° F. The large double incision united throughout by first intention, and the stitches were removed on the ninth day. As a precaution against hernia after such extensive incision of the abdominal walls, I have kept the patient upon her back, and will insist upon keeping her in bed for three weeks, by which time organization and consolidation of the incision will be complete. Her appetite is excellent, and all her digestive and eliminative functions seem to be carried on perfectly, which I interpret as an indication of good compensatory power on the part of the right kidney, and a guarantee of restoration to perfect health. This woman has naturally a strong constitution, has been accustomed to health-giving habits of frugality and industry, with temperate habits.

I herewith present for examination the sac of this large tumor which in its lower part still retains an outline of the form of the kidney. The fluid contained in this

cyst was not urine, but a perfectly clear fluid, such as we find in a typical par-ovarian cyst. It was an illustrative case of general cystic degeneration of the kidney, the capsule of the kidney forming a strong cyst wall, just as obtains in large ovarian cysts.

The practical lessons to be deducted from this experience are:

1. That in the diagnosis of abdominal tumors a large experience and painstaking investigation can not determine infallibly the exact character or even typical illustrations of ovarian tumors. The greater frequency of ovarian cysts alone determines a presumptive diagnosis between ovarian cyst and renal cyst. The exploratory incision is at last the means of positive diagnosis.

2. In operations presumably for simple, uncomplicated ovarian tumors the safety of the patient demands that the operator be qualified and prepared to deal with unexpected complications, and to do any operation known in abdominal surgery.

3. The results of nephrectomy, as shown by recent work, place this class of tumors within the limit of safe surgical procedures.

4. In dealing with large renal growths, and where nephrectomy may of necessity follow nephrotomy, the lateral abdominal incision in the semi-lunar line is preferable to the lumbar incision.

---

## IMPROVEMENT OF HEARING AFTER THE REMOVAL OF POLYPI AND GRANULATIONS FROM THE MIDDLE EAR.*

LOUIS J. LAUTENBACH, M.D., PH. D.†

Among the frequent conditions found in neglected suppurative otitis media are polypi and granulations. These are often looked upon as of very serious import, and as making the subjection of the inflammation more tedious and restorative of function well nigh impossible. In contradiction to this view I claim that restoration of function in these cases is more frequent as well as more thorough than in chronic suppurative cases of equal duration without granulations or polypi. I do not mean to say that this is invariably so, but that it is usually the case. In cases of chronic suppuration with these growths present, I feel more hopeful of stopping the discharge without an excision, of closing the perforation and especially improving the hearing. This conclusion has been reached as the result of some twelve years of special work and the examination and treatment of upward of fifteen thousand ear patients.

The explanation of this clinical fact is, perhaps, rather a difficult one. In long-continued suppurative cases without these growths we usually find a general sclerosis of the mucous tissues, the epithelium much changed in character and the membrane of the middle ear a scarred and cicatrized tissue binding down and distorting all the structures. In cases with polypi and granulation there is present a reparative process. As soon as the tissue become ulcerated, new tissue forms, sclerotic action here giving way to a proliferation. The cause of this difference may be the circulatory supply. In the sclerotic cases it is restored upon the removal of the growth. I have found that in such cases if the auditory nerve is intact, I have invariably improved or restored the hearing.

In a case treated in 1884, upon the removal of a polyp by the snare, the hearing was immediately improved, and within two weeks was normal. The same case was seen in February of this year, and was normal at that time.

In 1883, I treated G. S., Bristol, Penna., burned out a mass of granulations, and after six month's treatment he had perfect hearing, although there was a very large performation of the membrana tympani. His hearing in December, 1892, was still perfect.

March 3, 1893, examined Miss M. H., age 24. Both ears had been suppurating

---

* Read before Pennsylvania State Medical Society, 1893.

†Surgeon to the Pennsylvania Eye and Ear Dispensary; Chief of the Eye Clinic, German Hospital of Philadelphia.

for twenty-two years, occasioned by scarlet fever. Conversation heard with difficulty. Watch, right ear, 3½ inches; left ear, not on contact. Perforations posterior to handle of malleus occupied by granulations in both ears. Granulations removed. Hearing distance, April 28, watch, right ear, 12 inches; left ear, 5 inches. Conversation heard without effort. She considers her hearing perfect.

At present, I have under charge, Mr. F. H., age 21, Wayne, Pa., a case of entire destruction of the membrane, with breaking down of the mastoid cells, the result of an acute scarlatinous otitis of 15 years duration. The mastoid sinus was large, about 1¼ inches long. Occupying the middle ear cavity was a polyp, filling it entirely and interfering with the circulation to such an extent as to entirely occlude the meatus. Yet, despite these conditions, he is commencing to hear the watch a few inches from the ear and can hear ordinary conversation with effort.

These are but four, taken from some hundreds of cases, in all of which, when the treatment has been persisted in, the result has always been the same—either restoration or marked improvement of hearing.

---

## CLINICAL REPORT OF A CASE OF HEPATIC ABSCESS. *

A. J. BLOCH, M. D., New Orleans, La. †

I was called on the 30th of March last to see a gentleman, sent from the country by his physicians to see whether surgical treatment could not be of benefit to him. Mr. B. was a native of Louisiana; his family history was free from tuberculosis or syphilis. Prior to January, 1892, he enjoyed excellent health, at which time he was first confined to his bed by fever and pain in the right side. After prolonged medical treatment he experienced no relief, and came five months subsequently to New Orleans. This proving of slight benefit to him he returned home, and again came to New Orleans, this latter time five months ago. Being discouraged, having experienced no benefit, he determined to return home and die. Whilst on the train, he was suddenly taken with most violent pains in the affected side, and in another moment he coughed up what he supposed to be a quantity of blood, but which subsequently proved to be liver pus.

The diagnosis of his trouble was quite evident now; his general condition being so much below par, his physician at home placed him on cod liver oil, quinine and a cough mixture. They did not attempt a free incision to remove the septic material, not knowing exactly where to locate the pus cavity. Thus his condition remained, constantly coughing up pus continuous septic fever and great progressive emaciation.

Upon taking charge of his case, I immediately explored and located a pus cavity in the right lobe of the liver. I could not make out any definite destruction of lung tissue. There was an abundance of rales; these, however, might have been due to accumulated pus in the bronchial tubes. Dullness was well marked at the lower lobe of the right lung. It was quite evident to me that a chronic pneumonia must have supervened from a constant irritation of the septic material coughed up. The day following my first examination, I had him sent to the New Orleans Sanitarium, and, on April 1, under chloroform, I resected the rib and made a large opening into the abscess cavity, removing fully one pint of very foul pus.

Fearing to irrigate under chloroform, as the cavity communicated with the lung and the water might clog up the latter and produce death from asphyxia, I packed the cavity with iodoform gauze and had the patient removed to bed. The patient rallied well; his pulse, as before the operation, was 155 a minute; his respiration 40. The following day I irrigated with a

*Read before Orleans Parish Medical Society, April, 1893.

†Visiting Physician to Charity Hospital; Clinical Assistant to the Chair of Physical Diagnosis and Practice of Medicine, New Orleans Polyclinic; Assistant Instructor in Physical Diagnosis, Tulane Medical College.

2 per cent. solution of carbolic acid and substituted a drainage tube for the gauze. The change in his condition the next week was phenomenal; his temperature became normal; his pulse was reduced to 110, stronger and fuller; his appetite was inordinate, eating or asking to be fed whenever awake; his respirations from 24 to 28 a minute. He had been taking a tonic of iron and quinine, and when constipated a little sulphate of magnesia was given. Each day I irrigated the cavity with the carbolized solution, after which I injected peroxide of hydrogen, followed by iodoform and glycerine (4 drachms to 6 ounces). On April 15 I went to pay my daily visit. I found my patient in a very gratifying state; he complained a little of hiccough, but so confident did I feel in a future recovery that I promised to let him sit up in ten days. He was prepared to be dressed by the nurse in attendance, the patient assisting himself in the preparation. As soon as I introduced the nozzle of the syringe into the wound he began to cough; this was nothing unusual, as I experienced the same difficulty every day. I stopped for a moment, which gave him relief, and began again very gently to remove the pus. This time the cough became violent; my patient became cyanotic; I immediately grasped his pulse; it could not be felt; I tried every means possible to revive him, with no result; he was dead. I was unable to hold an autopsy and can account for his death to shock only, produced by a rupture of liver attachments, with flow of pus and water into the abdominal cavities, superinduced by the cough.

The points of interest in this case must be very apparent. Death might have ensued from several factors; firstly, from asphyxia or drowning the patient by irrigation; secondly, from shock resulting from a rupture of adhesions between the liver, abdominal wall and diaphragm. Another cardinal point is the danger of delay in making an early incision, to prevent a communication with the bronchial tube. Once this communication is formed the graver does the condition of our patient become. The constant passage of septic material through a lung, no matter how healthy, must leave destruction in its wake, and should we succeed in affecting a cure of the primary and graver trouble, we leave a suitable nidus for the propagation of the tubercule bacillus. I feel confident that my patient suffered from some such trouble.

The conclusion I draw from this case is: All suspected cases of liver abscesses should be explored early; a negative result will not increase the danger of the patient, a positive one will surely be of inestimable benefit. If pus is located an early incision should be made and the cavity thoroughly evacuated. If a communication has already formed with the bronchial tube irrigation should never be practiced, but in its place the cavity should be constantly packed with iodoform gauze. The latter will absorb the pus and disinfect the cavity and the patient will be spared the danger from which my patient died.

# SOCIETY REPORTS.

## THE CLINICAL SOCIETY OF LOUISVILLE.

*Stated Meeting, July 11th, 1893.*

Dr. L. S. McMurtry reported a

LARGE CYST OF KIDNEY; NEPHRECTOMY; RECOVERY.

(See page 368).

DISCUSSION.

Dr. W. L. Rodman; I take the position Dr. McMurtry does in these cases, that we cannot absolutely dispense with drainage in abdominal work. While in some instances it may be discarded, still a case of this kind emphasizes the necessity for it. I think the Doctor is to be congratulated upon the good result.

Dr. J. A. Ouchterlony: The case reported is remarkably interesting in many ways. I have seen a number of cases of cystic degeneration of the kidney, and yet I have never seen one having the least

resemblance to this. First of all in cystic degeneration of the kidney there are usually several cysts. The largest cyst I ever saw was a case reported by myself several years ago, it contained about a teacupful of fluid. All of the cysts had thin walls; they usually have extremely thin walls. Here is one single cyst with a thick wall and has the ureter entirely obstructed. No communication between the ureter and the cavity. It is difficult to picture to one's self exactly how this case began as there are no remains of the usual cystic formation.

Another interesting point about the case is that the disease was entirely limited to one side which is not the rule. In all cases of cystic degeneration of the kidney that I have hitherto seen, the disease was bi-lateral.

MILIA.

Dr. T. P. Satterwhite: I want to ask Dr. Bloom a question in regard to a form of growth that occurs particularly upon the eyelids, if he is familiar with the little growths called milium. The reason I ask the question is that I have a case in a child about nine years of age. For some time past he has had what I thought to be ordinary warts on both hands; they were very numerous, and he formed the habit of biting them off. Now, the mucous membrane of the mouth, particularly of the lower lip, is studded with these milium. My understanding has always been that milium were inoculable. However, in this case the growths seem to have communicated from the hands to the mucous membrane of the mouth. I would like to ask what Dr. Bloom's experience has been in this connection.

Dr. I. N. Bloom: Milia are very common and when opened are found to contain a small amount of cheesy matter and epithelium. No case of contagious milium was ever known.

CANCER OF RECTUM—EXCISION—RECOVERY.

Dr. J. M. Mathews: A gentleman was referred to me several months ago from Lexington, Ky., by our friend Dr. Skillman, for some rectal trouble. In giving the history he stated that there had been injected some preparation supposed to be carbolic acid, into some supposed tumors of the rectum; that they had sloughed off, giving him a great deal of pain, and in that particular he was slightly better but that in others he was worse. In making examination I was pretty well satisffed that he suffered from some malignant growth of the rectum, and I so wrote the Doctor. The patient returned home and five days ago came to the city for the purpose of being operated upon. I made a further examination and found a circumscribed growth taking in perhaps three to three and one-half inches of the lower rectum. That it was malignant I had no doubt, so I decided to operate. In saying that I decided to operate I mean that I decided to extirpate the growth, for I believe for many reasons this is far preferable to the operation which is being done most extensively by other operators for similar conditions; that is colotomy. I could easily circumscribe the growth, therefore believed that I could remove the whole mass. I submitted the proposition to him, stating at the time that the great fear would be that he might suffer from incontinence of feces, although in some other cases that I have on record, the contraction of the cicatrices has been sufficient to control the actions to a remarkable degree, at least. He accepted the proposition to operate, and, under anæsthesia I did the operation. It is not necessary to enter into details except to say that in this case I removed the coccyx to give me better room to operate by making a careful dissection, tying off the vessels as they were cut and pulling down the rectum with the growth, I cut it off. I did in this case as I have in others, and have several times been criticised for it, but the more I do it the more I am satisfied that I am pursuing the right plan; that is, I did not attempt to bring down the mucous membrane of the gut proper and stitch it to the true skin. I leave it expecting the wound to heal by granulation. My object is just this, to get cicatricial tissue, in order that the patient may control his evacuations. I watch the whole process carefully and see that there is no healing of the granulations to each other by apposition; in other words I keep different sized tubes in the rectum or anus until the wound is entirely healed.

I believe this man has a good chance of ultimate recovery from cancer. Of course the glands were a little involved, being

slightly enlarged in the inguinal region, but I believe these glands can be enlarged by inflammatory processes without being infected with cancerous material. At least this has been my experience in the past. I have often seen them so enlarged and so inflamed, and disappear after the operation.

This patient is only thirty years of age, has been a very healthy man up to a year ago when the symptoms were noticed, having no cachexia at all or other pronounced constitutional symptoms. I believe his chances of recovery are about the same as in the removal of the malignant breast of a woman; he suffered no further inflammation in the inguinal glands than perhaps would occur in the axillary space in malignant growth of the mammary gland in the female. This is the fifth day after the operation, and he has never suffered any pain—in three hours after the operation he complained a little but none since. I allowed his bowels to move to-day.

I speak of the case not that there is any unique feature in it, but principally to emphasize the belief that where extirpation can be done in malignant growths of the rectum, it is far preferable to the disgusting operation of colotomy.

DISCUSS ION.

Dr. W. O. Green, (visiting): I think Dr. Mathews pursued the proper course in this case. Cripps, Allingham, Treves and the majority of English surgeons state, I believe, that all cases should be operated upon where there is a fair chance of completely removing the diseased structures, and where the cancer is freely movable in all directions: Cripps points out in these cases that the most favorable ones are those in which the disease is limited to one side of the gut, resembles an ulcer, where the upper border is well marked, and healthy mucous membrane can be felt beyond the growth.

It is possible, where the disease is situated three inches up, to remove the malignant growth without interfering with the peritoneum and I believe this is the proper procedure under the circumstances. It is very important in removing cancerous growths from the rectum to know whether or not the peritoneum is opened. If it is, the chances of septic infection and subsequent peritonitis are greatly increased.

In regard to the prognosis: In the practice of American, English and Continental surgeons the direct mortality in excision of the rectum for cancerous growths is given at about 19 to 20 per cent. while the number of resultant cures of four years duration, have been shown not to exceed, at best, 11 per cent.

Concerning the cases that are suitable for operation: I think about fifteen to twenty per cent. of all cases of carcinomata of the rectum can be operated upon by excision.

Dr. Mathews spoke of not stitching the mucous membrane to the anus: I think he is quite right. In operations of this character the bowel can be stitched to the skin even where the gut has been removed some distance up, but the risks of peritonitis and cellulitis are far greater than otherwise. It is not likely that healing by first intention will take place on account of the great tension, much bruised tissues and number of ligatures required in closing the arteries. Healing by granulation suggests itself therefore as the proper course. In removing growths high up in the rectal pouch or there is an attempt to preserve the functions of the anus, a circular suture of the two ends of bowel is often practiced. Leakage has been shown to occur in fully half these cases. This, of course, establishes an artifical anus, which does away with the use of the natural anus and the dangers of septic infection are, consequently, much increased. I believe that, bearing in mind this liability of infection, when a circular incision is practiced a preliminary colotomy should be performed.

---

**Bacteria in the Soil at Different Depths.**

Some investigations carried out by Dr. Alexander A. Houston, of Edinburgh, respecting the number of bacteria in the soil at different depths from the surface, go to prove that the micro-organisms become less and less abundant as the depth from the surface increases. For example, the average number of germs in a gram of soil examined, which was taken from the surface, was 1,687,799; at a depth of three feet this average fell to 173,807; and at a depth of six feet it was anly 410. These figures are interesting, and would tend to show that at certain definite distances from the surface the soil would be sterile.

ISSUED EVERY SATURDAY

ADDRESS
Care P. O. Box 843, Philadelphia.

HAROLD H. KYNETT, A.M., M.D.,
Editor.

RODERIC C. PENFIELD,
Publisher.

316 = 18 = 20 North Broad Street,
PHILADELPHIA.

TERMS:—Five Dollars a year, strictly in advance, unless otherwise specifically agreed upon. Sent three months on trial for $1.00.

REMITTANCES should be made payable only to the Publisher, and when in sums of Five Dollars or less, should be made by Postal Note, Money Order or Registered Letter.

NOTICE TO CONTRIBUTORS:—We are always glad to receive articles of value to the profession, and when used they will be paid for, or reprints supplied, as the author may elect. Where reprints are desired, writers are requested to make a note of that fact on the first page of the MS. It is well for contributors to enclose stamps for postage, that the articles may be returned if not found available.

SATURDAY, SEPTEMBER 2ND, 1893.

## EDITORIAL.

### THE PRESIDENT'S HEALTH.

It seems a confirmed weakness of the secular press in dealing with the affairs of men prominent in public life, to announce them more or less incapacitated by illness —the habit of political opponents; or else suffering from an excess of good health— the habit of political supporters. So general is this custom of exaggeration that the public put little faith in reports on this subject. There is always a disposition on the part of friends to deny all rumors of sickness. This was notably so when Garfield was dying; also when Sheridan and Blaine were upon their death beds. The more prominent the man, the more he suffers—from press reports, so that when actually sick or threatened by impending death, the true knowledge of the matter comes like a shock to the public.

That it is fortunate the public is not generally aware of the truth is well illustrated in the present case of President Cleveland. The existing financial stringency, the confusion and uncertainty concerning the commercial interests of the country and other questions of vital importance to the nation, have brought about a condition of affairs that alarm for the chief magistrate's health would make "confusion worse confounded."

Sensational reports of President Cleveland's physical condition, together with some actions apparently inexplicable, have of late filled the secular press. The reports of ill health have been regarded in the same light as the reports of cowardice in meeting political emergencies. But it now seems that there was some foundation for the former reports, as it is asserted on what appears to be good authority, that not only was the President's health impaired seriously, but that he has submitted to an operation for immediate relief, and in hope of the ultimate cure of a serious condition.

It is stated that Mr. Cleveland has been suffering for some time from a morbid growth "in the bones of the left upper jaw and nose," the nature of which could only be determined by microscopical examination; the inference being that the growth was malignant. The diseased

portion of the bone was thoroughly removed without an external incision and the immediate recovery was complete. The operation was performed under nitrous oxide anæsthesia, while the President was on board of a friend's yacht on the first day of July last. None but the most intimate friends of the President were cognizant of his condition or of the performance of the operation at the time.

President Cleveland's wonderful self-control and endurance, and his intense devotion to the duties of his position have excited the admiration and respect of all, even his political opponents. The hope that the growth will prove benign, or if not, that the operation was entirely radical, will be universal. Doubtless the profession will soon be aware of the actual nature of the disease.

## TRANSLATIONS.

### INTRA-UTERINE INJECTIONS IN PUERPERAL INFECTION.

Ouimet (*L' Union Med. du. Canada* April, 1893) states that in 1750 intra-uterine injections were first introduced into France in the treatment of puerperal complications. In 1853, Eisenmenger in Germany, made injections of charcoal water in a case of putrid infection. As to the *mode of action of intra-uterine injections*, it is recognized to-day that puerperal infection is a septicemia due to the absorption of pus formed in the uterine cavity. When delivery has been complete there is nothing but the uterine mucosa to suppurate, but in the contrary case, there is added to this the putrefaction of the debris of the ovum or of a clot retained in the uterine cavity. Consequently, to cure the puerperal infection it is necessary to meet two indications: to prevent the absorption of pus by removing it, and to arrest suppuration. Intra-uterine injections have this double power, and they also have a mechanical and a therapeutic action. The mechanical action consists in the removal of the contents of the uterine cavity, and M.M. Budin and Auvard have demonstrated the truth of the statement that intra-uterine injections bathe thoroughly the entire uterine cavity. The injection by removing from the uterine cavity the putrefying substances causes rapidly an amelioration in the general state and a fall of the fever. This rapid effect has been observed by all investigators but it has only been since the introduction of antisepsis that we may observe actual cases of cure or very rapid amelioration. By removing the septic products the injections suppress the cause of general infection of the organism, because the absorption of pus ceases. If the infection is quite superficial and the disinfection complete by the first injection, there is no reproduction of pus, the fever falls and a cure is produced. The antiseptic agents act upon the surface and not in the depth of the tumor, so that when the infection is deeper the injections have a slighter action, and it is necessary to make two, three, or even ten or eleven injections in order to make a cure. In truth the antiseptic agent has disinfected the surface but the septic products contained in the deeper layers are eliminated, and it is necessary to repeat the injection to remove them. The antiseptic agent acts in an analogous manner upon foreign bodies, membrane, clots or placental debris, which the uterus nearly always contains in cases of infection. Under the influence of antiseptic injections their putrefaction is arrested more or less rapidly, and they are eliminated as detritus without suppuration. During this local action the general state ameliorates progressively, because by hindering the absorption of new septic products, the injections permit the organism to eliminate the products already observed without undergoing a new weakening from the absorption of a new quantity of septic products. In order that the antiseptic action be efficacious it is necessary that the injected fluid remain a certain time in contact with the mucosa. To meet this condition it is necessary to pass a very large quantity of

† Translated for The Medical and Surgical Reporter by W. A. N. Dorland, M. D.

fluid into the uterine cavity, four to six liters at each injection.

*Therapeutic Indications.*—It is evident that the action of intra-uterine injections is most prompt if the infection is superficial. It is therefore proper to begin the treatment early. An injection should be made each time that there is an elevation of temperature that cannot be manifestly attributable to a cause foreign to the uterus. If an examination of the placenta shows that there remain portions in the uterine cavity, or if there be a peculiar offensive odor of the lochia, there are indications that the uterus is infected and that injections are required. In a slight case, when the temperature does not exceed 38° C, it will suffice to make one injection daily. If the temperature be more elevated, two or three injections should be made daily, especially if the infection is produced by the putrefaction of a foreign body. During the past ten years very many antiseptic substances have been employed in obstetrics; salicylic acid, thymol, boric acid, permanganate of potash, are those that are most serviceable for intra-uterine injection. Since the introduction of the bichloride of mercury by Professor Tarnier, this agent is nearly universally employed for intra-uterine injections. It is necessary to employ a 1 to 4000 or 5000 solution. Albuminura, by hindering the rapid elimination of the poison in case a certain portion be absorbed, is a formal contra-indication to its employment. In this case carbolic acid,2 to 100, should be employed. The injecting fluid should have a temperature of from 30° to 35° C. At each injection it is necessary to use at least 4 to 5 liters of the fluid. The injection of the sublimate should always be followed by the injection of one or two liters of boiled water to prevent absorption of the fluid that remains in the uterus and vagina, an absorption facilitated by the wounds in these organs.

*Accidents.*—Intra-uterine injections, while constituting a powerful means in the hands of the physician of combatting puerperal infection, are not absolutely without danger. Some of the objections offered to their use are theoretical, others are real:

1. *Passage of the liquid through the tubes.* This objection is purely theoretical; experimentation has always demonstrated its falsehood and clinical observation has never proved it. On the contrary, experiments on cadavers, and clinical observation prove that this danger does not exist, and it becomes necessary to consider as strongly hypothetical the possibility of the passage of an injected fluid through the tubes into the peritoneal cavity.

2. *Entrance of air into the uterine sinuses and thence into the circulation.* This is also an entirely theoretical objection. Nevertheless, to prevent this danger, it is proper not to introduce the sound into the uterus until it is completely deprived by air.

3. *The production of hemorrhage.* To prevent this accident it is necessary to avoid much pressure, and to provide oneself with a perfectly sound and smooth instrument.

4. In some cases are observed acute and transient symptoms, consisting in chills, renal pains, acceleration of the pulse, cyanosis, syncope, convulsive movements. These may be attributed to fear, impressionability, hysteria, sudden distension of the uterus, too low temperature of the fluid.

5. *Perforation of the uterus.* In the introduction of the sound it is not necessary to employ force. It should glide in of itself. Perforation may result from an obstacle to the free passage of the sound; from undue softness of the uterine tissue, or from a bad direction or undue force applied to the sound to overcome an obstacle. This is a very grave accident, and probably the only one to fear. To avoid it violence should never be employed, and should the sound meet with an obstruction, it is always well to ascertain its nature before executing a manœuvre to overcome it.

*Conclusions.* 1. Intra-uterine injections constitute a rational and efficacious treatment in puerperal infection.

2. They should be made with a sound which assures the easy flow of the liquid and a complete lavage of the uterine cavity.

3. The sound of M. Baudin fills these condition; also that of M. Doleris.

4. If the sound meets with an obstacle in its passage it is necessary always to ascertain its nature and never to employ force to free it, because the softness of the uterine tissues renders possible its perforation.

.5 The injections are made with a solution of bichloride of mercury 1 to 5000; in case of contra-indication, with carbolized water 2 to 100.

# ABSTRACTS.

## CHOLERA: ITS PREVENTION AND TREATMENT.

Dr. Elmer Lee, of Chicago, says:

The leading propositions suggested and tried in the treatment of Asiatic cholera during the epidemic of 1892 in Europe, consisted of the following general plans. Early in the epidemic, lactic acid treatment was proposed on the ground that it would neutralize the alkaline accumulations in the bowels and so stop the multiplication of the bacilli.

The use of large doses of salol grew in favor as a new remedy during the epidemic. The average result of cases so treated could not be said to be satisfactory.

Calomel was everywhere a remedy even more used than salol. Formerly this drug was used in very large doses, but last year it was the very small doses which found favor. Especially was this true in the treatment of cholera in Hamburg.

Of the surgical measures, the infusion of solutions of salt were most practiced. The solution consisted of distilled water in which was dissolved one-half of one per cent. of common salt. This liquid was warmed to the temperature of the blood and either introduced directly into some large vein or injected with a long needle and a large barrel syringe beneath the integument of the abdomen. The amount of salt solution used in either case would be from one pint to one quart each time. In one case treated at Hamburg as much as thirteen quarts of salt-water were used from first to last. The patient recovered. The subcutaneous injections were frequently followed by cysts and sometimes abscesses appeared. Intravenous injections sometimes proved a godsend, but more frequently disappointment could be said to be the result. These injections were only used in the third period of the disease or the stage of collapse, algidity or asphyxiation, at which period, it would be rather unreasonable to expect recovery by virtue of any treatment.

The Italian treatment was much used and with frequent gratifying success. It consists of a clyster composed of the following constituents:

℞

| | |
|---|---|
| Boiled water or infusion of chamomile, (warm) | 2 litres. |
| Tannin | 5 to 10 grams. |
| Laudanum | 30 to 50 drops. |
| Powdered gum-arabic | 50 grams. |

This or some part of the solution is occasionally passed into the rectum, to be retained if possible by the patient. In the experience of those who have followed this method of treatment almost every case taken at the beginning of the disease has lived. It is certainly more reasonable in principle than simple medical management.

Of the experiments of Ferran, of Spain, and Haffkine of the Pasteur Institute, much has been said, but what has been said has failed to bring conviction to my mind. As cholera itself cannot be said to protect one who has had the disease, and recovered, against a second attack, then that which is less than cholera in influence cannot be expected to do it. The seat of the disease is located in the intestines, and, so long as the infectious juices are there, the lymph vessels in the processes of physiological function will continue to infect the blood. Can we hope to thwart physiological action of absorbents by hypodermic injection of cholera culture, made at some time, it may be years previous to the date of the passing epidemic? The answer by my judgment, is that such expectations are flimsy.

It is now well known that cholera is a disease of the alimentary canal. Its inciting cause is believed to be a germ taken into that canal through the medium of food and drink. There its presence is protested against by the absorbent vessels, which eliminate from the food the nutriment for the body. The first symptom produced by foreign invasion in the intestines is a diarrhœa, which may precede vomiting from one to three or even four days. If this be true, the bowels must be the seat of disorder, and the most direct method of reaching them by medication must be the best. If the stomach could be emptied of the foul material before the poison has passed further, there might be speedy relief and, indeed, no real cholera. After it has passed into the intestines, medicine administered through the stomach may be slow in reaching the seat of the disease, and even then can only mingle with the poison, holding out the hope that the one will be neutralized by the other. This hope, in truth, is seldom

realized. But if the poison can be removed from below, the course is left clear for nature to recuperate itself. The diarrhœa is an evidence of the great exertion put forth by the organism to rid itself of the death-dealing agency, and probably it would be effectual in the great majority of cases were it not that the nervous forces of the system are exhausted by the terrible strain before the required evacuation of the bowels is completed. A large irrigation of hot water, made soapy preferably by neutral liquid soap, introduced into the colon through a suitable rubber tube, is the simplest, and I am prepared to say further that it is a more satisfactory way of treating cholera than any other with which I am acquainted. The time to begin the irrigation is at the very earliest possible moment. The rule from which there need never be deviation is to treat the patient by irrigation of the bowels and rinsing of the stomach, without waiting for confirmation of the diagnosis either with the microscope or by the culture test. The best part of the practice is always to save the patient, even at the expense of fine statistics.

For internal treatment my experience taught me that the *peroxide of hydrogen*, given in cupful doses of the strength of 4 per cent., or even much stronger was a better antiseptic than any other drug heretofore known in the treatment of cholera. Then the treatment would be, first, immediate irrigations with hot water and soap, using from one to three gallons at a time twice a day for the first and second day. Once a day afterwards if required, which is seldom the case. At the same time cleanse the stomach with *peroxide of hydrogen* and hot water used freely—by urging the patient to drink. The feeding and nursing are the same as would be required by a patient suffering from septicæmia or other prostrating disease.

Cleanse the bowels, wash the stomach, feed the sick, keep them warm if cold, and reduce excessive heat by the cool bath rather than reliance upon drugs; using anything in an emergency that is the easiest and the most accessible to procure. The cholera patient may be convalescent inside of the first few days, or if not convalescent and not dead, the case goes into the typhoid state, after which convalescence may be deferred for several weeks or death may be the conclusion. The temperature prior to the fifth day is generally subnormal or a little above, but on the fifth day marked exacerbation and elevation of temperature indicates the typhoid condition.—*Chicago Clin. Rev.*

## PHARMACOLOGY IN EUROPE.

Piperazin is steadily gaining ground in the estimation of European physicians, and is regarded as *the* remedy in all forms of uric acid diathesis in continually widening circles. Dr. H. Wittzack brings the latest contribution to the literature of the subject, and his experiences are equally favorable as those of Bisenthal and others who have fairly tried the remedy in practice. From observations in five cases of gravel and in one case of arthritis urica deformans, he draws the conclusions, that (1) diuresis is considerably increased, in the case of arthritis, the amount passed in the twenty-four hours being more than doubled; (2) the specific gravity and acid reaction of the urine is lowered, but never becomes alkaline or even neutral; (3) the appetite is not affected and no disturbance of the general condition can be attributed to the administration of piperazin; (4) that there is no difference in the action of free base piperazin and its hydrochloric acid salt, but in practice the salt is preferable because it is less hygroscopic. The author further emphasizes the necessity of administering piperazin continuously for some days (15 grains daily for a fortnight) before forming an opinion as to its efficacy, and at the same time describes subcutaneous injections of piperazin as both painful and dangerous, causing infiltration and a tendency to form an abscess.

The main outcome of Wittzack's experiments is that he conscientiously recommends piperazin in all cases of uric acid diathesis and regards it as a specific remedy. A similar favorable opinion is held by Dr. John Gordon, who at the request of the Scientific Grants Committee

of the British Medical Association undertook to test the power of solution possessed by piperazin on uric acid and uric acid calculi, and its therapeutic value in cases of gout or in uric acid diathesis. In his preliminary report on the first points in the research, he says, that there is distinct evidence of its solvent power both of calculi and uric acid. As yet clinical cases have not been obtained in sufficient numbers to allow him to draw conclusions as to its therapeutic action.

Piperazin is, however, still too new a remedy to escape objections against its employment, which mainly depend upon incomplete acquaintance with the characters of the base. Thus Dr. Roerig a short time ago reported a most unpleasant bye-effect of piperazin, which, if true, might well have raised grave doubts as to the advisability of its administration. He observed that after administration of piperazin to two persons suffering from uric acid diathesis the urine gave a copious precipitate with picric acid, and he at once rushed to the conclusion that albuminuria was induced by the action of the piperazin upon probably unsound kidneys. This result, however, was in distinct contradiction to the observations of earlier investigators who had administered as much as 90 grains piperazin *pro die* without finding albumen in the urine. The fallacy was, at once, evident when Biesenthal pointed out that even with 1 part piperazin in 20,000 parts water picric acid produces a distinct precipitate, so that considering the large proportion of the base that passes through the organism undecomposed there is no wonder that a precipitate is formed by this reagent in the urine after administration of 15 or 30 grains piperazin. The correctness of this opinion has been practically demonstrated and the nature of the precipitate more nearly investigated. Employing picric acid as reagent the distinction between albumen and piperazin is best shown by the disappearance of the crystalline precipitate of piperazin picrate on warming, whilst the albumen compound is insoluble both in hot and cold water. In the light of this knowledge Dr. Roerig's observations lose their startling character.

Instead of the employment of piperazin being limited it appears rather to be extending to new fields of usefulness. Dr. Hildebrant found that piperazin possesses the property of completely overcoming the elimination of sugar from dogs poisoned with phloridzin. By simultaneous administration of phloridzin and piperazin the usual diabetic symptoms did not appear, and the general condition of the animals remained good, the hydrochloric salicylic and phosphoric acids being equally active. The application of this treatment to a severe case of diabetes, by the administration of 15 to 25 grains piperazin *pro die,* given in 3 doses in aqueous solution, and persisted in for 14 days, reduced the sugar percentage from 7 or 8 to 3.3 per cent., whilst the general condition and nourishment of the patient was improved.

As the results of an investigation by Dr. Sittmann of the value of papain in stomach affections, the author found that it developed its digestive action alike in neutral, alkaline and acid solution, and in cases of absence or pathological change of the digestive juices reduced the albumen to an assimilable condition. He administered 5 to 8 grains papain (1½ grains sufficed to digest 150 grains coagulated egg albumen in 4 ounces of water in 2 hours), mixed with a little water, immediately after every meal of flesh. In acute catarrh of the stomach the improvement was noticeable after 2 or 3 doses, the pain disappeared, appetite increased, and in 2 or 3 days a complete recovery was affected, more than 6 doses never being required. In chronic catarrh the course of treatment required to be prolonged for a fort-night; in three cases of chronic dyspepsia, originating in ulcus ventriculi, the appetite was restored in a week. Even in 2 cases of carcinoma ventriculi, that ultimately underwent a post-mortem examination, the use of papain considerably diminished the pain after meals. It was also successful in neurosis of the stomach, and in hysterical and neurasthenical cases. It is evident, therefore, that papain is a valuable agent in maintaining the general assimilative conditions for a time in all cases where there is, from any cause, failure of the digestive juices of the stomach.

The fact that papain has the power of digesting and thereby destroying dead and diseased animal matter, whilst it is inactive towards healthy living tissue is also not sufficiently appreciated by surgeons. Although papayotin was originally introduced by Rossbach for the local antiseptic

treatment of diptheritic membranes, it has now been replaced by the cheaper and more active papain. Yet even this has fallen somewhat into disuse, and there is no doubt that the reason consists in its having been used too sparingly. As it is non-poisonous it can be applied freely without danger. In a recent contribution by Dr. H. A. Francis on the uses of papain as a "selective caustic" he relates that in his experience all traces of diphtheritic membrane disappear in a few hours in cases where the powder can be insufflated freely and frequently. In tuberculous ulceration he has also applied papain with success, and notably in lupus vulgaris In the latter case a saturated solution of papain in glycerin was given to be rubbed into the lupous patch night and morning. The papules gradually disappeared, the surface assumed a healthier appearance, and even became soft and flexible and only slightly discolored, the ulceration having completely healed.

It is astounding what conflicting reports appear as to the employment of pental as an anæsthetic, and although from time to time unpleasant and even fatal consequences are attributed to its use, as is the case with all anæsthetics, yet the fact that pental always finds a host of partisans, especially among dental surgeons, who maintain that they can employ it with comparative safety and without the disagreeable after-symptoms that accompany most anæsthetics, leads one to suppose that want of success is as much due to inexperienced manipulation or accidental circumstances as to any inherent defects in the compound. In a paper by a lady-doctor, Fraulein Kleindienst, a new development presents itself. Although the author concurs with Professor Hollander and others as to the action of pental on frogs and rabbits, and as to the happy results obtained in minor operations, having even administered it with success in anæsthesis lasting 48 minutes without any untoward symptoms, yet she condemns its use because she believes to have observed an injurious action on the kidneys, having detected in a few cases albumen and blood in the urine after pental narcosis. This evidence being so entirely new requires support before it can be accepted, especially as in two cases in which details are given, it appears that zinc chloride injections were made during the operation, and zinc chloride is known to injuriously effect the kidneys.

The direct consequence of this communication has been that Dr. Bauchwitz has made a special series of experiments to determine the truth of the appearance of abnormalities in the urine after pental narcosis. The results of his examination of the urniue, both of rabbits and human beings, are completely negative, nor was he able to detect any organic changes in the kidneys of rabbits killed by overdoses of pental. In fact, in his experience in operations on the teeth and mouth, pental is at present the best anæsthetic we possess for short operations, in consideration of its reliability and general condition of the patient after the operation.

Calomel is a drug so well known that any reference to its use almost calls for an apology, but the experience of Dr. C. Chapman of the advantages of repeated small doses of calomel over the usual dosage is worthy of attention. Fractional doses appear indicated in cases of gastro-intestinal catarrh, whether following upon exposure to cold or from improper feeding, where the stomach is intolerant alike of medicine and of food; a similar plan has also been of great service in adults with protracted vomiting, where the more obvious causes for the sickness have been eliminated and the only additional symptoms have been an independent pain in the hepatic region and an abnormally red tongue. In two illustrative cases quoted by Dr. Chapman, one a child of four years, the other a woman 54 years old, the symptoms were due to catarrh of the upper part of the alimentary tract associated with some hepatic congestion. To the child the following powders were prescribed: Calomel, one grain; sugar of milk, eight grains;—to be divided into ten powders, one to be placed on the tongue every fifteen minutes. To the adult the calomel was given in doses of one-sixth of a grain every twenty minutes until two grains had been taken. The earlier beneficial effects of the calomel is probably to be attributed to the germicidal and antiseptic properties of the mercury, as the stomach speedily became more tolerant of food, and the breath lost the odor suggestive of fermentation, before the liver could have been acted upon by the drug, though improvement was more marked after the

bowels had been acted upon. Gardiner has also exhibited calomel in a similar manner with gratifying results.

Most interesting is, however, the applicability of this mode of treatment in the later stages of heart disease, where long-standing valvular disease has by backward pressure caused the well-recognized visceral complications, amongst which may be noted congestion and catarrh of the alimentary tract consequent upon the chronically gorged state of the liver. It is obvious that digestion and and assimilation, being thus interfered with, not only does the general nutrition suffer, but the already enfeebled and dilated heart yields more and more. Dr. Chapman cites a case of heart failure in which, after all other medicines had failed, doses of one-sixth grain calomel every half hour, and nutrient enemata, restored the patient, apparently at the point of dissolution. Here relief of the portal congestion is probably the most important effect of the calomel; the right side of the heart, feeling first the lessening of the pressure, is able to do its work better; the hepatic cells resume to some extent their function; and the kidneys, sharing in the general relief of the tension, cause a decrease of the jaundice and lessoning of the œdema. The appetite returns in due course.

In hospital use chloralamid continues to elicit favorable expresssions of opinion in regard to its hypnotic qualities, especially in different forms of mental disturbances. Früs gives it in the form of an alcoholic mixture; Chloralamid 10 parts, alcohol 20 parts. syr. aurantii 30 parts, and water 100 parts: the dose for adults being as a rule one to two teaspoonfuls pro die. He has given it in 47 cases with satisfactory results, the action being prompt except in advanced cases of delirium tremens, in which it was without effect, as well as unreliable in the insomnia of males due to chronic alcoholism. Its administration is not attended with any injurious bye-effects upon the digestive organs, even after employment for months, and the heart's action is in no wise affected. The pulse and respiration, in the author's experience, remain quiet and regular under the hypnotic influence of the drug.

A novel employment for the new antiseptic, formalin, has been found by Dr. Hauser, of Erlangen, which indirectly demonstrates the extremely powerful and penetrating action of formic aldehyde and, paradoxical as it may seem, relates to the preservation of bacteria. It is evident that in the teaching of bacteriology demonstrations of pure cultures of bacteria in gelatine and as plate cultivations are invaluable and almost indispensable aids. Mary authors have tried in this way to prepare and preserve cultures on different media with only partial success. The vapor of formalin, which contains about 40 per cent. formic aldehyde, have a most extraordinary disinfecting power, so that not only the surface is attacked but the development is checked and the micro-organisms killed in the deepest layers. Not only so, but in gelatine cultures by the continuous action of the formalin vapors the gelatine liquefied by the bacteria is again solidified without losing its characteristic appearance, so that in this manner Dr. Hauser has been able to preserve plates of cholera, anthrax, typhus, proteus, staphoylococcus, sarceria, and other bacteria, retaining both their microscopical and macroscopical characters unaltered. The method is very simple, the vessels containing the cultures being simply covered with a piece of filter paper moistened with 10 to 15 drops of formalin and placed in a moist closed chamber, in which is also placed a procelain dish containing cotton-wool saturated with the disinfectant. It is important that only fresh formalin should be employed for this purpose, and that it has not been exposed in badly closed bottles.—*Notes on New Remedies.*

### Hæmaturia.

Bloody urine alternating with clear urine is almost a positive sign that the region of the trouble is in the kidney, as this condition of things never exists in disease of the bladder. If the last of the urine shows clear blood, or appears to be most bloody, it locates the trouble in the bladder, the contractions forcing out the blood. In a case where the urethra is free from disease, blood showing mostly at the beginning of micturition proves the trouble to be located at the neck of the bladder.—*Annals of Gynecology and Pædiatry.*

Sodium Sulphate, in strong solution, introduced into the stomach through a tube, if the patient is unable to swallow is reported to be an efficacious antidote in cases of poisoning by carbolic acid.

# THE LIBRARY TABLE.

## BOOK REVIEWS.

*Hospitals and Asylums of the World.* Their origin, history, construction, administration, management, and legislation; with plans of the chief medical institutions. By Henry C. Burdett. In four volumes and a portfolio. London: J. & A. Churchill. Vols. III and IV.

These volumes conclude the most elaborate discussion of this subject that has ever been published. The author is especially well qualified for his work and has displayed remarkable energy and perseverence as well as rare judgment in treating his subject. He states in his preface that his work has cost him fourteen years of labor and a large sum of money and when the obstacles to be overcome are taken into consideration, his remark that it has been "a labor of love is entirely superfluous."

The first two volumes have already been noticed in the REPORTER. The third volume discusses the origin and history of hospitals, systems of hospital administration, revenue and expenditures, system of nursing, dispensaries and special forms of hospitals including military and naval. The discussion of the practical financial problems is elaborate and while referring more particularly to English institutions, is well worth study by all interested in the management of hospitals. It would be well if the conclusion he reaches as to the folly of narrow economy in hospital finance could be deeply impressed upon the managers of such institutions in this country as well as abroad. He notes that large hospital endowments are rarer in America than in Europe. Also that the income from pay patients is greater here than there. Elaborate tables give the average yearly expenditure per bed in various hospitals, and the great difference between hospitals in this respect is due to the peculiarities of individual institutions and the work done by them. In general, small hospitals expend more per head per annum than do large ones.

The chapter on the organization and management of nursing systems in connection with hospital work is excellent, though that part relating to the United States is too condensed. The discussion of the relation of hospitals and medical schools showing that the connection is of mutual benefit, is of great interest and importance. This relationship has never been sufficiently insisted upon in this country. We believe every hospital where charitable work is done should be a means of instruction and benefit easily accessible to medical students.

The fourth volume, together with a large portfolio of plans, is devoted to hospital construction and incidently to institutions intimately associated with hospital work. To expert hospital architects this part of the work is indispensible, and the information, while technical, can be easily understood by any intelligent person. The author insists that those charged with the responsibility of hospital construction should place the entire matter in the hands of an expert, thoroughly acquainted with the most recent deoɟəʌpments in hospital needs and administration, and not in the hands of those inexperienced in this particular branch, however expert in others. Neglect to follow this advice will invariably prove its wisdom though the demonstration be costly.

The volume includes types of the best modern hospitals and of them all the highest praise is given the Johns Hopkin's Hospital in Baltimore, which the author says "is by far the most complete and perfect set of buildings which have ever been erected for hospital use." The section on hospitals for infectious and contagious diseases, with the plans for such buildings, will be a Goloconda of information for municipal authorities in America at this immediate time.

The work is well printed on good paper and neatly and strongly bound, and since the edition is limited to 500 copies, those interested in this subject should secure the work without unnecessary delay.

*The Ready-Reference Handbook of Diseases of the Skin.* By George Thomas Jackson, M. D. With Fifty Illustrations. Philadelphia: Lea Brothers & Co. 1892.

This volume is intended to present the art of dermatology as it now exists. No attempt has been made to discuss debatable questions. Hence, pathology and etiology do not receive as full consideration as symptomatology, diagnosis, and treatment.

The alphabetical arrangement of the different diseases has been adopted for convenience of ready reference. The descriptions of various diseases are clear, lucid and careful.

Attention is called to the fact that in the prescriptions given no attempt has been made to translate grains, drachms, and ounces into their precise equivalents in grammes, but simply to preserve the relative percentages of the ingredients in the old formulæ and express them in decimals. The decimals may be regarded as either grammes or parts.

The work is divided into two parts with an appendix. Part I. comprising some 28 pages, is devoted to the Anatomy and Physiology of the Skin, Diagnosis, Therapeutic Notes, and Some Dermatological Dont's. Part II. The Diseases of the Skin and their Treatment. In the present state of our knowledge it is impossible to make a satisfactory classification of skin diseases. Many attemps have been made to do this, and are still being made. Nearly every systematic writer tries his hand at it with more or less indifferent success. Hebra's classification, modified, is found in a great many textbooks. The arrangement of this book does away with classification, with which the student need not burden his mind.

The Appendix contains 13 pages of formulæ, given as guides in the preparation of

prescriptions for the treatment of skin diseases. Many, if not all of them, have been tried by the author and their value proved.

*Dunglison's New Pronouncing Medical Dictionary.*

A new edition of Dunglison's Medical Dictionary is announced as in press for early publication. It has been thoroughly revised and greatly enlarged, and will contain about forty-four thousand new medical words and phrases. Pronunciation has been introduced into the new edition by means of a simple phonetic spelling. This work has always been noted for the fullness of its definitions, ample explanation being its distinguishing characteristic. In the new edition much encyclopœdic information, difficult of access elsewhere, will be found conveniently at hand. Especial attention has been devoted to matters of practical value. A review will appear in an early issue.

*A New Medical Dictionary.* A completely new Medical Dictionary is announced for early publication by Lea Brothers & Co.

The author, Dr. Alexander Duane, of New York, is already widely known as the medical expert for Webster's International Dictionary. His new work has been drafted to supply medical students with all desired information concerning the words they will meet in their course of reading, and as the vocabulary has been selected most liberally, the work will be of value to practitioners also. The pronunciation of each word is given by a simple and obvious phonetic spelling; then follows the derivation, an unexcelled aid to memory, and finally a full definition. Descriptive matter has been appended to such words as cannot be adequately explained by simple definition. Thus diseases are described, and their symptoms and treatment are given; drugs are followed by their properties, effects, doses, etc. Extensive tables of bacteria, doses, etc., are placed in the alphabet most conveniently for reference. A work of real value is promised, and we shall take an early opportunity of reviewing it in these columns.

*The Review of Reviews*

Seems to hold the most intimate relations with almost everything and everybody in all parts of the world. Its illustrations and its bits of summary discussion put its readers into harmonious acquaintanceship with nearly all that is worth remembering in the events and the discussion of the preceding month.

In this period of depression when a good many older periodicals have been hard beset, it is interesting to learn that the *Review of Reviews*, although comparatively so young, has won a position as impregnable as any other periodical that could be named in the United States, and that its circulation is not only solidly maintained, but steadily increasing through the intrinsic merits of the periodical. The *Review* has become a necessity to a large constituency; and whereas in times of financial depression many people give up their luxuries, there is always a steady market for the plain necessaries. Fortunately for the *Review of Reviews*, its readers consider it as a prime requisite rather than a causal luxury, and so its editions are not curtailed by the influence of current financial disasters.

Sharp & Dohme's Price List for 1893.

Special mention is made of Webber-pepsin, Ergotole, Pan-Peptic preparations and other special products. This will prove a convenient reference book for the profession to whom copies samples and literature will be sent upon application.

# PERISCOPE.

## MEDICINE.

### Antidote for Carbolic Acid.

An Italian tailor swallowed by mistake thirty grammes of carbobic acid. Dr. Moreit, of Ancona, using a rubber catheter, immediately introduced by slow degrees into the patient's stomach a strong solution of sulphate of soda, which forms with corbolic acid a harmless mixture. In an hour's time the patient, who had een in a most critical condition, began to revive, Inhalations of ammonia were then used to hasten up the process, and little by little the poisoned man rallied so that an emetic, followed by a dose of lime-water, finished the cure.—*Med. Times.*

## SURGERY.

### Tape-worm the Cause of Rupture of the Intestine.

Dr. F. Dunlap (*New York Med. Jour.*, February 11, 1893) mentions a case of intestinal rupture occurring in a woman of thirty-one years of age, apparently caused by a tape-worm. When first seen the patient complained of violent pains in the left iliac region, followed in several hours by profound collapse. Rupture of an ectopic pregnancy was suspected, the suspicion being encouraged by the fact that menstruation had been absent for several months. A boggy mass was to be felt in the abdomen, and abdominal section was decided upon and performed. A

mass of clot was found in the pelvis, but the pelvic organs were found in a normal condition; nor could any aneurism, which had been thought of, be found. In flooding the cavity a long tape-worm was floated to the surface, and tracing it towards the head, it was found to protrude from a large, ragged rupture in the small intestine. It was fastened about twelve inches above the seat of rupture. Eight feet of the worm were removed from the peritoneal cavity, and about seventeen feet more were passed from the bowel afterwards as the result of an enema. From examination it appeared that there had existed no previous ulceration at the site of the rupture, the ragged gangrenous edges suggesting rather a pressure gangrene. The patient recovered.

## OBSTETRICS.

### Spontaneous Rupture of the Symphysis Pubis During Labor.

Oelschlager (*Centralbl. fur Gynakol*) has reported the case of a primipara, twenty years old, in which with the onset of labor pains two eclamptic attacks occurred in quick succession. The lower extremities were edematous, and the urine contained a small amount of albumin. The promontory of the sacrum could be touched with two fingers introduced into the vagina. The head was quite high in the pelvis and but slowly followed in the grasp of the forceps, a not excessive degree of traction being exercised. As the head began to rotate in the small pelvis a crack was distinctly heard. Examination disclosed a separation of 1.15 inches in the situation of the symphysis pubis, and the delivery of a living child weighing nine pounds was soon readily effected. On the day following the labor a leather support was applied to the hips. For two weeks the region of the symphysis was tender upon touch and painful upon movement, but a week later the woman was able to be up and about, although a slight degree of separation of the pubic bones persisted.

## GYNECOLOGY.

### Removal of a Lithopedion Thirty Years in the Body.

Gottschalk (*Centrallbatt f. Gynak., Med. Jour.*), exhibited before the German Obstetrical Society, in March, a lithopedion five pounds in weight, successfuly removed by abdominal section after it had been carried thirty years, causing more or less inconvenience to the patient at different times. The patient was 54, and had passed the menopause four years before. Her first pregnancy was thirty-three years ago, and the child lived. During the second and last, extrauterine pregnancy was diagnosed. Towards term, violent pains set in, which ceased together with the fetal movements. Peritonitis ensued, and kept her several months in bed. Thenceforth she recovered gradually and was regular till the menopause. The indication for abdominal section was the appearance of severe symptoms of obstruction, especially in the direction of the bladder. The symptoms were clearly due to the impaction of a hard substance, the fetal skull, in the pelvic cavity. The uterus was pushed upwards and backwards against the sacrum, flattened by the fetus, which was as hard as a rock. The tumor reached as high as the umbilicus. The left Fallopian tube ran normally over it, and Gottschalk declares that the fetus, well-preserved, lay entirley within ovarian tissue. The sac-wall was clacified, the placenta still adhered to its inner surface.

## NEWS AND MISCELLANY.

### Announcement—College of Physicians of Philadelphia.

The William F. Jenks Memorial Prize. The Third Triennial Prize, of Five Hundred Dollars, under the Deed of Trust of Mrs. William F. Jenks, will be awarded to the author of the best essay on "Infant Mortality During Labor, and its Prevention"

The conditions annexed by the founder of this prize are, that the "prize or award must always be for some subject connected with Obstetrics, or the Diseases of Women, or the Diseases of Children;" and that "the Trustees, under this deed for the time being, can, in their discretion, publish the successful essay, or any paper written upon any subject for which they may offer a reward, provided the income in their hands may, in their judgment, be sufficient for that purpose, and the essay or paper be considered by them worthy of publication. If published, the distribution of said essay shall be entirely under the control of said Trustees. In case they do not publish the said essay or paper, it shall be the property of the College of Physicians of Philadelphia."

The prize is open for competition to the whole world, but the essay must be the production of a single person.

The essay, which must be written in the English language, or if in a foreign language, accompanied by an English translation, should be sent to the College of Physicians of Philadelphia, Pennsylvania, U.S.A., before January 1, 1895, addressed to Horace Y. Evans, M. D., Chairman of the William F. Jenks Prize Committee.

Each essay must be typewritten, distinguished by a motto, and accompanied by a sealed envelope bearing the same motto and containing the name and address of the writer. No envelope will be opened except that which accompanies the successful essay.

The Committee will return the unsuccessful essays if reclaimed by their respective writers, or their agents, within one year.

The Committee reserves the right not to make an award if no essay submitted is considered worthy of the prize.

JAMES V. INGHAM,
*Secretary of the Trustees.*

### An Army Medical Board

Will meet at Washington City, D. C., October 2nd, 1893, for the examination of candidates for appointment to the Medical Corps of the United States Army, to fill existing vacancies.

Persons desiring to present themselves for examination by the Board will make application to the Secretary of War, before September 15th, 1893, for the necessary invitation, stating the date and place of birth, the place and State of permanent residence, the fact of American citizenship, the name of the medical college from whence they were graduated, and a record of service in hospital, if any, from the authorities thereof. The application should be accompanied by certificates based on personal knowledge, from at least two physicians of repute, as to professional standing, character, and moral habits. The candidate must be between 22 and 28 years of age, and a graduate from a Regular Medical College, as evidence of which, his Diploma must be submitted to the Board.

Further information regarding the examinations may be obtained by addressing the Surgeon General U. S. Army, Washington, D. C.

GEO. M. STERNBERG,
*Surgeon General U. S. Army.*

## CIRCULAR OF INFORMATION

FOR CANDIDATES SEEKING APPOINTMENT IN THE MEDICAL CORPS OF THE UNITED STATES ARMY.

The Medical Corps of the Army consists of a Surgeon General with the rank of brigadier general, six Assistant Surgeons General with the rank of colonel, ten Deputy Surgeons General with the rank of lieutenant colonel, fifty Surgeons with the rank of major, and one hundred and twenty-five Assistant Surgeons with the rank of 1st lieutenant, mounted, for the first five years and the rank of captain, mounted, thereafter until promoted to major. Promotion through the intermediate grades of rank from that of captain to that of colonel is by seniority, but there is an examination for the rank of captain and another for that of major, to ascertain the fitness of the officer for promotion. Advancement to lieutenant colonel and colonel takes place without further examination. The Surgeon General is selected by the President from among the members of the corps. All vacancies are filled by appointment to the junior grade.

PAY AND EMOLUMENTS.

To each rank is attached a fixed annual salary, which is received in monthly payments, and this is increased by ten per cent. for each period of five years' service until a maximum of forty per cent. is reached. An Assistant Surgeon with the rank of 1st lieutenant, mounted, receives $1,600 per annum, or $133.33 monthly. At the end of five years he is promoted to captain and receives $2,000 a year, which, with the increase of ten per cent. for five years' service, is $2,200, or $183.33 per month. After ten years' service he receives $2,400, after fifteen years $2,600, and if he remains a captain after twenty years, $2,800 per year. The pay attached to the rank of major is $2,500 a year, which, with ten per cent. added for each five years' service, becomes $3,250 after fifteen years and $3,500 after twenty years. The monthly pay of lieutenant colonel, colonel, and brigadier general is $333.33, $375, and $458,33 respectively. Officers in addition to their pay proper are furnished with a liberal allowance of quarters according to rank, either in kind, or, when no suitable Government building is available, by commutation. When traveling on duty an officer receives four cents per mile and reimbursement of money actually expended for railroad or other fares. On change of station he is entitled to transportation for professional books and papers and a reasonable amount of baggage at Government expense. Mounted officers, including all officers of the Medical Corps, are provided with forage, stabling, and transportation for horses owned and actually kept by them, not exceeding two for all ranks below a brigadier. Groceries and other articles may be purchased from the Commissary and fuel from the Quartermaster's Department at about wholesale cost price. Books and instruments are supplied in abundance for the use of medical officers in the performance of their duties.

ARMY MEDICAL SCHOOL.

By a recent order the Secretary of War has authorized the establishment of an Army Medical School in the city of Washington for the purpose of instructing approved candidates for admission to the Medical Corps of the Army in their duties as medical officers.

The course of instruction will be for four months, and will be given annually at the Army Medical Museum, in Washington City, commencing on the 1st day of November.

Four professors will be selected from among the senior medical officers of the Army stationed in or near the city of Washington, and as many associate professors as may be required to give practical laboratory instruction in the methods of sanitary analyses microscopical technique, clinical microscopy, bacteriology, urine analysis, etc.

The faculty of the Army Medical School will consist of—

1. A *President of the Faculty*, who shall be responsible for the discipline of the school, and who will deliver a course of lectures upon the duties of the medical officers in war and peace (including property responsibility, examination of recruits, certificates of disability, reports, rights and privileges, customs of service, etc.).
2. A *Professor of Military Surgery* (including the care and transportation of wounded).
3. A *Professor of Military Hygiene* (including practical instruction in the examination of air, water, food, and clothing from a sanitary point of view).
4. A *Professor of Clinical and Sanitary Microscopy* (including bacteriology and urinology).

DUTIES AND PRIVILEGES.

A medical officer after completing the course of instruction at the Army Medical School will be assigned for some months as junior at a large military post in order that he may become acquainted with Army regulations, and making of official reports, and other matters necessarily new to him, before he is thrown upon his own responsibility. His stations after that are likely to alternate between the frontier and more desirable points, a tour of duty being usually four years at one place. Leave of absence on full pay is allowed at the rate of one month per year, and this when not taken may accumulate to a maximum of four months, which at the end of four years is then available as one continuous leave. Beyond this an officer may still be absent with permission on half pay.

It is the intention of the Surgeon General to recommend the assignment for duty, as attending surgeons in the principal medical centers of the United States, of medical officers who have not yet passed their examinations for promotion to a majority and, so far as may be practicable, in the order of their seniority. These details will be made for one year only, in order that as many medical officers as possible may be enabled to avail themselves of the opportunities thus offered to become familiar with the practice of the leading physicians and surgeons in this country, and of attending medical lectures, meetings of medical societies, etc. At the end of this tour of duty medical officers will be required to make a detailed report to the Surgeon General showing how much of their time has been occupied by their official duties and to what extent they have availed themselves of the advantages offered for professional advancement.

Absence from duty on account of sickness involves no loss of pay. Medical officers are entitled to the privilege of retirement at any time for disability incurred in the line of duty or after forty years' service. On attaining the age of sixty-four they are placed upon the retired list by virtue of statutory provision. Retired officers receive three-fourths the amount of their pay proper at the time of retirement.

EXAMINATION AND APPOINTMENT.

Appointments to the Medical Corps of the Army are made by the President after the applicant has passed a successful examination before the Army Medical Examining Board and has been recommended by the Surgeon General. The board usually meets twice a year, about April and October, of which due notice is given by advertisement. Permission to appear before the board is obtained by letter to the Secretary of War, which must be in the handwriting of the applicant, giving the date and place of his birth and the place and State of which he is a permanent resident, and inclosing certificates based on personal acquaintance from at least two reputable persons as to his citizenship, character, and habits. The candidate must be a citizen of the United States, between twenty-two and twenty-eight years old, of sound health and good character, and a graduate of some regular medical college, in evidence of which his diploma will be submitted to the board. The scope of the examination will include the morals, habits, physical and mental qualifications of the candidate, and his general aptitude for service; and the board will report unfavorably should it have a reasonable doubt of his efficiency in any of these particulars.

The physical examination comes first in order, and must be thorough. Each candidate will in addition be required to certify "that he labors under no mental or physical infirmity or disability of any kind which can in any way interfere with the most efficient discharge of any duty which may be required." Errors of refraction when not excessive, and not accompanied by ocular disease, and when correctible by appropriate glasses, are not causes for rejection.

The mental examinations are conducted by both written and oral questions, to which written and oral answers are required upon—

I. Elementary branches of common school education, including English grammar, arithmetic, the history and geography of the United States, natural philosophy, the principles of Latin grammar, and upon general literature and ancient and modern history. Candidates claiming especial knowledge of the higher mathematics, ancient or modern languages, drawing, analytic chemistry or other branches of natural science, will be examined in those matters as accomplishments and will receive due credit therefore according to their proficiency.

II. Professional branches, including anatomy, physiology, chemistry, hygiene, pathology and bacteriology, therapeutics and materia medica, surgery, practice of medicine, obstetrics and the diseases of women and children.

Examinations at the bedside will also be conducted in clinical medicine and surgery, and operations and demonstrations upon the cadaver.

Hospital training and practical experience in the practice of medicine, surgery, and obstetrics are of great importance to candidates seeking admission to the Medical Corps of the Army, and they will be fully appreciated and duly credited to those who have had such advantages.

The board has discretion to deviate in such manner as it deems best from this general plan of examination when necessary for the interests of the service.

To save unnecessary expense to candidates, those who desire it may have a preliminary physical examination and a mental examination in the "elementary branches of a common school education," by a medical officer of the Army stationed most conveniently for this purpose, who will act under instructions from the Medical Examining Board.

The merits of the candidates in each of the several branches, and also their relative merit as evinced by the results obtained from the entire examination, will be reported by the board, and in accordance with this re-

port approved candidates will be appointed to existing vacancies or to such as may occur within two years thereafter. An applicant failing in one examination may be allowed a second after one year, but not a third. No concession vill be made for the expenses of persons undergoing examination, but those who receive appointments will be entitled to travel allowances in obeying the first order assigning them to duty.

There are at present six vacancies in the corps to be filled.

## ARMY AND NAVY.

U. S. ARMY FROM AUGUST 20, 1893, TO AUGUST 26, 1893.

By direction of the Secretary of War, a board of medical officers to consist of: Col. Charles H. Alden, assistant surgeon general; Lieut. Col. Wm. H. Forwood, deputy surgeon general; Major Chas. Smant, surgeon; Captain Walter Reed, assistant surgeon and Captain James C. Merrill, assistant, is constituted to meet at the Army Medical Museum Building, in this city on the 11th day of September, 1893, for the examination of candidates for admission to the Medical Corps of the Army.

Par. S. O. 93 Hdgrs. of the Army, A. G. O., Washington, Aug. 23rd, 1893.

By direction of the Secretary of War the following-named medical officers are detailed to represent the Medical Department of the Army at the Pan-American Medical Congress, to be held in Washington, D. C., September 5th to 8th, 1893. Colonel B. J. D. Irwin, assistant surgeon general; Lieut. Colonel Dallas Bache, deputy surgeon general; Major David L. Huntington, surgeon; Major Charles Smant, surgeon.

Board of officers to consist of: Colonel Charles H. Alden, assistant sugeon general; Lieut. Col. Wm. H. Forwood, deputy surgeon general; Major Joseph K. Corson, surgeon, is by direction of the Secretary of War, appointed to meet at the Army Medical Museum Building, Washington, D. C., Monday, September 4th, 1893, for the examination of such officers as may be ordered before it, to determine their fitness for promotion.

Lieut. Col. Wm. D. Wolverton, deputy surgeon general, is relieved from duty at Waterolict Arsenal, N. Y., and assigned to duty as medical director, Department of the Columbia, to relieve Lieut. Col. C. C. Byrne, deputy surgeon general, U. S. Army.

Lieut. Col. C. C. Byrne, deputy surgeon general, on being relieved from duty as medical director, Department of the Columbia, will report for duty as medical director, Department of Dakota, to relieve Colonel Charles H. Alden, assistant surgeon general.

Colonel Charles H. Alden, assistant surgeon general, on being relieved from duty as medical director, Department of Dakota, will proceed to this city and report to the Surgeon General U. S. Army, for duty in his office, and as president of the Army Medical School, Washington, D. C.

Leave of absence for one month, with permission to apply for an extension of ten (10) days, is hereby granted to Captain J. L. Powell, assistant surgeon U. S. Army.

By direction of the Secretary of War the following named officers will report in person to Colonel C. H. Alden, assistant surgeon general, president of the examining board appointed to meet at the Army Medical Museum Building, September 4th, 1893, for examination for promotion: Captain Curtis E. Price, assistant surgeon; Captain E. T. Comegys, assistant surgeon; Captain Walter Reed, assistant surgeon; Captain James C. Merrill, assistant surgeon.

Leave of absence for one month, to take effect upon the return of Assistant Surgeon Glennan from leave, is granted Captain Wm. F. Carter, assistant surgeon.

Major Justus M. Brown, surgeon, is relieved from duty at Fort Meade, South Dakota, and assigned to duty at Fort Wayne, Michigan.

Leave of absence for one month, to take effect about September 1st, 1893, is granted Captain Paul Shillock, assistant surgeon, (in the field) with permission to apply for an extension of fifteen days.

The commanding officer U. S. Troops in the field near Fruitland, N. M., is authorized to employ a citizen physician in cases of necessity during absence of Captain Paul Shillock, assistant surgeon.

Leave of absence for one month is granted Captain R. J. Gibson, assistant surgeon U. S. Army.

### MATERNITY HOSPITALS AND THEIR RESULTS.*

JOSEPH PRICE, A. M., M. D., Philadelphia, Pa.

Every obstetrician's dependence in emergencies must be upon himself. If the resources of his information and skill are so limited that he must call in extraneous aid, the lying-in woman is exposed to other risks than those of delay—those of dangerous drugging or ignorant surgical interference. The resourceful surgeon is one with many experiences, and the same fact applies to the successful obstetrician. The lessons of three or four hundred maternity cases never yet made an eminently skillful obstetrician — one to be depended upon in all of the many emergencies liable to be met with in lying-in cases.

The problems, those tests of the practical wisdom of hard earned and well learned lessons, of the very genius of obstetrical skill, arising in many emergencies give no time for settlement by consulting the books, by reference to reported cases or by calling in outside aid. In fact the lessons of the books in many cases would be misguiding. Through many and painful experiences, the lessons of sad results, we have unlearned many of the teachings of the old books.

There is grand promise in the fact that the profession of the period has in it the impulse and the spirit to grow away from and above the old benches. One of the most gratifying and hopeful results of the thorough training which comes of wide obstetrical experience is the doing away with the too free use of instruments in delivery.

Certainly with the lessons of more than two centuries of forceps experience we should be able to form an enlightened opinion as to the value or risks of their use. The consensus of the best authorities, of the opinions of men who speak from the most extended observation and experience, leads to the conclusion that the mortality attending non-interference is less than that attending the use of forceps. In this relation our debt is great to the Dublin school of obstetricians. Dr. Clark, for long master of the Rotunda, stands out as the one heroic figure in the van of those pioneers.

The exigencies requiring the use of instruments are not of such frequent occurrence as formerly believed. Now the citing of a case of instrumental interference is usually accompanied by an elaborate statement and explanation of desperate and otherwise unavoidable conditions. We have learned the evil and bad results of hurry; the welfare of mother and child are no longer to be sacrificed to the exigencies of private practice. With the growth of general intelligence our patients become less tolerant of undue haste, they have an enlightened appreciation of the issues involved, and of well-timed and skillful work, and they make few mistakes in their book keeping, in charging to the correct cause unhappy or fatal results. It is not a wild prophesy when we say that the time is not distant

* Read before Pan-American Medical Congrets, 1893

when in all dense communities obstetrics will be a specialty, and in the ranks of its practitioners there will be the cleanest, most cultured and scientific men of the profession. The issues, the often fearful sequelæ of ignorant or ill-advised treatment in cases of midwifery, furnish a strong warning, a resistless argument against the employment in such practice of the inexperienced and unskilled.

The advantage of patients in maternities over private lying-in patients lies in the fact that they are under the strict surveillance of experienced medical men, aided by nurses trained in all the principles and methods of their art. All the environs and appointments are under the control of well defined and intelligent authority,—sanitary and hygienic conditions are of more easy control, the evils of dense crowding can be avoided, and an ideal cleanliness more nearly attained. There are less injuries in maternities from attempts to expedite labor. And from this cause there are more evil consequences than from delay or any other cause; nature is interfered with in doing her part of the work. There is no branch of medical science in which we have so many understood certainties as in obstetrics.

Where our knowledge is defective or incomplete, it is not due to lack of authentic source, of easy and approved means—but to the lack of energy of use. There exist open opportunities of bed-side experience and training, many open doors for clinical study and research, yet there are very many—and the best—kept closed. For this the profession is responsible. It is their mission and duty to heal—it is also their mission, duty and royal right to the use of every avenue through which the best lessons are taught. The tyros going out from our college benches into fields of private practice are ill-equipped for successful obstetrical work, they carry many risks to mothers. We are not claiming that the science or its practice in the hands of any one is perfect,—that cannot be claimed of anything in which our humanity is involved.

There has been gathered a very rich harvest of the results of cleanliness in maternities and private obstetrical work, and we have in these results promise of yet better results in the future. As we grow to know how very simple is our art, how near to nature is its successful practice, we feel less disposed to take off our hats when we speak of our individual work and its success.

It has not been long since obstetrics was the one department and dominated the field of gynecology. Progress has been such that gynecology no longer suffers the reproach of being a pseudo-science, working by guess, by vague suspicion, gaining advances by mere experiments upon human life, groping in the dark in attempts at settlement of problems of health and life, but has grown to work hand in hand with obstetrics and is gaining increased recognition whereever suffering exists. The lessons of both have come to live with us. In both experience teaches the value of cleanliness—that we have no right to tolerate filth in any of its forms—nor to blunder in our work.

The signal advances in obstetrics as in gynecology are of our own generation. As to many anomalies, obscure troubles, the general practitioner has become enlightened, he has acquired the important knowledge which enables him to determine where purely medical or palliative treatment fails, and the only resource left is surgical interference. The obstetrician is not practicing what his forefathers wore out and threw away. Old theories and beliefs have been gradually giving way before the assault of our better facts. Each day finds fewer superstitions in practical medicine and surgery. Dr. Angus Macdonald in a Report of the Royal Maternity and Simpson Memorial Hospital, Edinburgh, condenses truths worthy of mention here: "The more I see of midwifery and gynecology, the more I am confirmed that the safety of patients urgently requires the diligent use of cleanliness. I feel more and more satisfied that operations on the genitals, of whatever sort, are specially dangerous, not so much because of the inflammatory reaction, which is likely to be severe in itself as because there is extreme facility for septic absorption. This is particularly the case where, from aggregation of septic influences, there is specially apt to arise putrescent materials of highly toxic qualities."

The reduction of the mortality in lying-in hospitals from 20 per cent. to almost nil cannot be credited so much to the use of antiseptics as to a more enlightened and strict sanitary regime, a more strict

cleanliness. The constant improvement in our operative statistics testifies the value of surgical cleanliness, scrupulous aseptic precautions. The great increase in the average of city life is largely due to greatly increased observance of health conditions. The measure of the physician's responsibility in these lines cannot be over-estimated.

He can kindly, where that will serve, or sternly, where that is needed, urge the lesson that to live amid bad hygienic conditions, in an atmosphere of domestic malaria means disease and death,—that pure, healthy in-door air, freedom from poisonous effluvia and musty odors, cannot be had without the most scrupulous cleanliness, the removal of all bodily excretions, of everything offensive; animal, fluid and organic. There are out-door impurities, sources of air pollution, we cannot at all times and under all circumstances wholly guard against. Streets, alleys and courts are often sources of atmospheric infection over which we have little or no control. The most we can do is to educate public sentiment in the line of a wise sanitary policy and back its administration.

The members of the medical profession have it in their power to make themselves the sovereigns in the enforcement of the wise dicta of sanitary science. They are the real educators in everything that pertains to the public health. The people are willing and anxious to learn the lessons through the practice of which they can avoid disease. The more the obstetrician and medical men generally, press home upon the public the vital truth of the preventibility of many diseases, the sooner we will have a popular understanding of the simple principles of sanitary science and a rigid practice of cleanliness. Let the physician teach the risks of filth infection to his clientele—send the lesson into private homes that bedding, carpets, floors, walls, every appurtenance and furnishing may be a source of uncleanness, that all forms of excretia and impure gases emanating from decaying organic substances are so much pollution.

The apology for this paper, if any be needed, lies in the importance of the subject, its importance to the profession, to communities, and its yet more grave importance to mothers. I would echo the voice of Holmes loud enough for warning. "The woman about to become a mother, or with her new-born infant upon her bosom, should be the object of trembling care and sympathy wherever she bears her tender burden, or stretches her aching limbs. The very outcast of the streets has pity upon her sister in degredation when the seal of promised maternity is impressed upon her. The remorseless vengeance of the law, brought down upon its victim by a machinery as sure as destiny, is arrested in its fall at a word which reveals her transient claim for mercy. The solemn prayer of the liturgy singles out her sorrows from the multiplied trials of life, to plead for her in the hour of peril. God forbid that any member of the profession to which she trusts her life, doubly precious at that eventful period, should hazard it negligently, unadvisedly, or selfishly!"

I presume a long and somewhat varied experience entitles me to speak plainly and the time for speaking plainly is always present, always *now*. As to the *conscience* with which I speak, that is mine. There are some things about which our national and inter-national medical congresses should speak in no uncertain tones; there are some things that we here at home and our honored brothers of Republics to the south of us should insist upon, everything associated with our profession, with our schools and all their agencies, with respective fields and departments of practice, is a sacred trust. A trust something more than narrowly individual, it is communism in all that it involves, its bond is to prolong and promote healthful human life. The trustees of our schools and maternities hold the highest trust existing in our communities, a trust that reaches helpless mothers and their more helpless off-spring, that reaches the unfortunate in every grade of life, and humanity is their care. Yet they only too frequently do not exercise wisdom and deliberation in the choice of teachers and masters. The time is fortunately not distant when they will be held to more strict account. We have long since proven that maternal deaths are avoidable, deaths not only from sepsis or child-bed fever, but from other causes as well, death in child-bed means an error of omission or commission. The mortality in maternity hospitals is now the lowest. Maternities have settled about all the important disputed points in obstetrical practice. The most perfect work has

been done in the maternities of Baltimore, Philadelphia, New York and Boston. Not only has this work been perfect from the standpoint of a low mortality, but the hospitals in which it has been done have done a great work in practical teaching, demonstrating beautifully two points: 1st, That a maternity can be run with a nil mortality; 2nd, That it can unite with its humane purpose practical teaching with a nil mortality. All this has been disputed both at home and abroad. The time is not distant in the future when the directors of maternity hospitals will not dare to appoint a man to direct or have official charge of such vital interests without a rich practical experience and sound judgment. They will be held responsible for the success of their trust, and it is to be hoped will be held criminally responsible for the choice of a person to such trust with no more pride of personal cleanliness and cleanliness of environment than a stable boy, dirty in all the term implies, morally and personally.

It is the teaching of this subject that is of so much vital importance to the profession. Very much of it is fed out from the old books and is worth very little more to the student than is an old almanac for dates. The student gets little of clinical or practical value and goes out from the college to study the science and art of his work upon helpless patients. Every day brings to our notice sad illustrations of the result of such miserably poor and inadequate obstetrical teaching. The directors or managers of our schools are responsible for imperfect, inadequate or false teaching; the profession and the community must and do so hold them responsible. They hold them responsible for the incompetent and unfit men they select to teach; for the injustice done worthy students and for the irreparable mischief worked in communities by obstetrical ignorance. Teachers should not be appointed on account of their pedigree, their family connections or their wealth, but for their brains, their knowledge of their subjects, their love and faculty for teaching, and for the honor and advancement of the school. About all some of those now holding responsible chairs in some of our oldest schools have to recommend them is a volume of prefixes to their names, suggestive of a medical and biographocal index. The shout goes up when doting relatives, maiden aunts and friends who secure their appointment "Now we have a professor of favored parentage, one dating beyond our accepted scriptural Genesis." At the claims of this class the Darwinian would indulge a philosophic smile and note fresh evidence in favor of his theory of the descent of the human species. There should be no small men, mentally nor morally, in the faculties of our great schools. The work of none of us is so well done but that it cannot be out-done—better done. Let each man go back and study the history of his own neighborhood in connection with obstetrical practice and he will scarcely escape being startled by the result.

Recently, within the past few weeks, several lovely women, those moving in the most cultured and refined of Philadelphia society have died in child-bed. Now these untimely and sad deaths are too frequent. In a majority of instances they are avoidable by the exercise of enlightened precautions, through the practice of that skill which comes of experience and without which no man should enter a lying-in-chamber. The old mock, tearful reverence, the pious humility with which the deaths in these cases are credited to providential dispensation will not longer answer. With each death the demand will grow stronger, more universal and angry for better and more thorough obstetrical teaching.

I speak for the pride and best hope of our land, the American student; for the best loved, the purest and noblest of our own or any other land, our American mothers.

---

The Year of greatest growth in boys is the seventeenth; in girls the fourteenth. While girls reach full height in their fifteenth year, they acquire full weight at the age of twenty. Boys are stronger than girls from birth to the eleventh year; then girls become superior physically to the seventeenth year, when the tables are again turned and remain so. From November to April children grow very little and gain no weight; from April to July they gain in height, but lose in weight; From July to November they increase greatly in weight, but not in height.—*British Medical Monthly.*

# TOTAL EXTIRPATION OF THE SCAPULA WITH THE ARM RETAINED.*

A. M. PHELPS, M. D.†

Mr. John N. B., of Mount Vernon, aged forty-two years, consulted me on November 21, 1891. I found a large

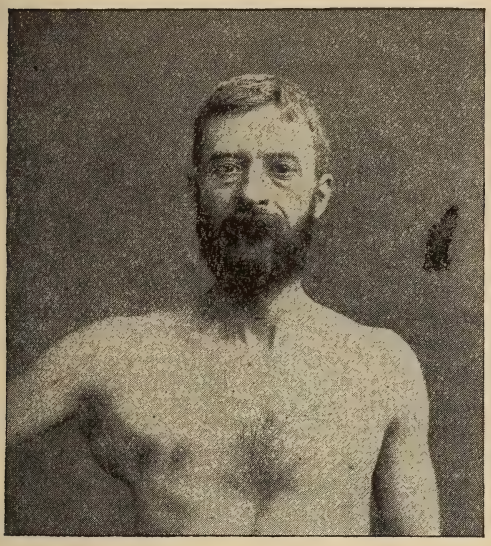

*Fig. 1.*

tumor, growing from the scapula, and involving its entire extent. Figures 1, and 2, convey a very correct idea of the extent of the deformity. He first observed the growth three years ago, as a hard, irregular mass, growing from the anterior border of the scapula. It has not been attended by pain until quite recently. He did not know what caused it.

I find that the tumor extends to the axilla, and up under the pectoral muscles, the scapula being somewhat movable. The tumor is nodulated, and the glands in the axilla are enlarged. His general health is good; his occupation is a book-keeper.

Dr. W. T. Bull and Dr. Robert T. Morris in consultation, advised extirpation of the scapula, and, if possible, saving the arm and clavicle. I proceeded to operate upon the case at the Post-Graduate Hospital, Doctors Plimpton Mooney, Kelly, and the house-staff assisting. The incision made was that of Langenbeck—see *A*. figure 2. This incision was from the upper and inner angle of the scapula, extending along its spine to the tip of the acromion process. Another incision was carried at right-angles with this line, to the inferior angle of the scapula. The arm was then severed from its attachment to the scapula. The superior flap was now turned upwards, the supra-scapular and posterior scapular arteries being secured; the inferior flap was quickly turned backwards, exposing the posterior border of the scapula, which was then tilted forwards and dissected from its base, the dissection including all of the muscles attached to the scapula, the infra-scapular artery being secured as the dissection proceeded. The scapula was cut away from its attachment to the clavicle, the muscles detached from the coracoid process and the whole removed *en masse*. A few bleeding points were now secured, and the deltoid muscle stitched carefully to the fibrous tissue

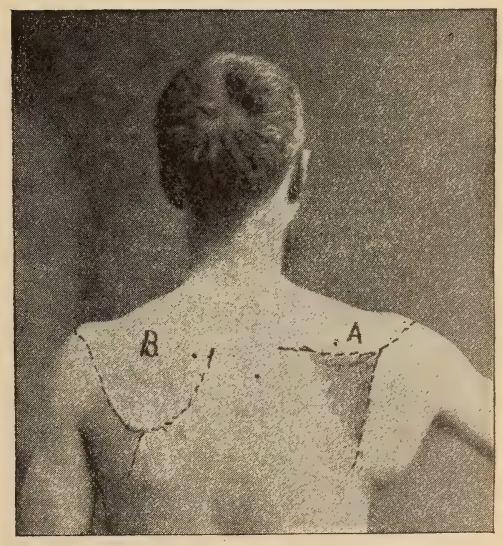

*Fig. 2.*

A. Langenbeck's incision showing slough.
B. As it should be from an anatomical standpoint.

about the end of the clavicle, the head of the bone resting well up underneath

*Read before the Surgical Section of the Academy of Medicine.

†Professor Surgery University of Vermont; Professor Orthopædic Surgery University Medical College N. Y.; Professor Orthopædic Surgery N. Y. Post-Graduate School and Hospital.

the acromion end of the clavicle. The wound was next carefully stitched up and dressed antiseptically, and the whole suspended in a sling to the side of the body.

The tumor was found attached to the second and third ribs quite extensively, and was with very great difficulty separated; the time of the operation, including the dressings was 57 minutes. There was no shock, and no higher temperature than 101° following the operation. At the first dressing, it was discovered that the inferior angular flap had sloughed (see *A*, fig. 2). This sloughing of the flap was caused by want of nutrition. The supra-scapular and posterior scapular arteries supply this portion of the flap and by Langenbeck's incision they were both cut. Then again, the angular portion of this flap, shelving up over the head of the

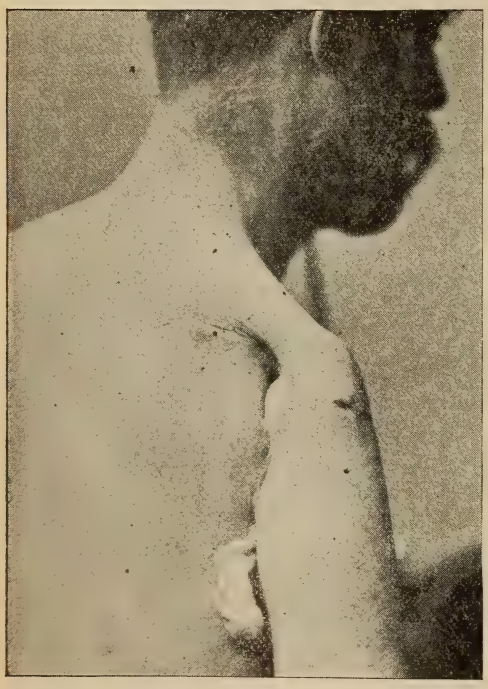

*Fig. 3.*

bone, did not come in contact with the subjacent tissue, therefore sloughing necessarily followed. This I found upon inquiry, was not an uncommon result where the Langenbeck incision was employed. To remedy this, I suggest that the incision and flap be made as in figure 2, *B*. This will secure a flap properly nourished by the supra-scapular and posterior scapular arteries, and probably would not slough; it certainly is an incision which should be tried, because the sloughing of the flap retards the healing process and endangers the life of the patient. The wound healed without pus, and the patient was discharged from the hospital at the end of three weeks.

Two weeks after his discharge, he was attacked with "la grippe," and one week or later, six weeks after the operation, he began coughing, and raised large quantities of pus. Dr. Wilcox diagnosticated a circumscribed empyema in the upper lobe of the lung. His report is here appended:

January 2nd, 1892. Contracted a severe catarrhal bronchitis. At that time dullness to middle of second rib on right side; line of dullness horizontal and running to vertebral spines.

Jan. 4th. Night sweats; cough out of proportion to severity of bronchitis; hectic; great prostration; absolute flatness in area noted above; distant respiration; vocal fremitus and resonance markedly diminished.

Jan. 7th. Empyema ruptured into secondary ascending bronchus of upper lobe of right lung. Six ounces of light colored, diffused pus evacuated.

Jan. 9th. Empyema ruptured into inferior outer angle of wound. One-half ounce of similar pus discharged. Direct connection between bronchus and wound, the cavity of which was cleared by coughing.

Jan. 12th. External orifice closed. Tympanitic percussion note over region named; high pitched amphoric respiration; few tenaceous rales.

Jan. 16th. Opening into bronchus closed; signs of slight dullness; somewhat distant respiration; few crepitant (pleural) rales.

Jan. 19th. Bronchitis entirely cured.

Feb. 1st. A traumatic exudative pleurisy had closed some of chest.

Feb. 2nd. Infection of this exudate from purulent bronchitis and not from wound.

Feb. 3rd. Resulting empyema.

Feb. 4th. Positive diagnosis from physical signs, when the contents of empyema measured less than seven ounces.

Feb. 5th. Adhesive pleuritis preventing general pneumothorax after rupture.

Feb. 6th. External opening allowing free emptying of pus cavity (important therapeutic indication).

Feb. 7th. Rapid healing of pus cavity by secondary exudative pleuritis.

This empyema opened into the bronchus and also externally at the upper border of the wound. From this time on recovery was rapid. The empyema was not produced by the trauma or by infection, but was due entirely to the attack of "la grippe," and was simply a coincidence. The wound was healed perfectly by April 4th, 1892. One observation which we made was that the exposed end of the humerus was entirely healed over at the end of forty-two days, the cartilage was gradually absorbed by granulations appearing through it, and the skin did not grow over the head of the bone until the cartilage was entirely removed by the granulating process. Although the power of motion at the shoulder is limited, the hand and arm are useful.

An examination made by Dr. Smith, the pathologist of the Post-Graduate Laboratory, showed that the tumor was made up entirely of fibrous material, and was not malignant. It is interesting to note that in this condition of non-malignancy, were found the nodulated appearance of sarcoma, the pain attending on sarcoma, and the enlargement of the glands which we would expect to find in malignant disease, or in sarcoma which was undergoing destructive changes. The patient up to date has remained perfectly well. There has been no return of the disease and to all appearance, he is a well man.

I have examined the literature upon the subject of total extirpation of the scapula, the arm and clavicle being retained and find up to the date of this operation, that there have been 118 cases reported, 58 of which were for tumors, 9 for caries and injury, 51 not reported upon. There were 25 deaths, 3 undetermined. The age varied from 8 to 70 years; the mortality was 22 per cent.

The conclusions at which I arrived are: (1) total extirpation of the scapula is not an extremely dangerous operation to perform, if care is taken to cut in such an order as to secure the supra-scapular, posterior scapular, and infra-scapular arteries; (2) in cases of malignant disease attended by extreme vascularity, I would suggest that the subclavian artery between the coracoid process and the thyroid axis be compressed by means of a large curved needle, transfixing all the tissues, carrying underneath everything a silk ligature which would be tied temporarily, thus controlling the hemorrhage. It will be remembered that the scapula receives its vascular supply superiorly from the thyroid axis, which is given off from the subclavian; (3) that Langenbeck's incision should not be used for the reasons already given. The curved incision which I suggest (fig. 2, *B.*) is based upon the vascular anatomy of the parts.

---

### The Patent Medicine Business.

Light has been let into the patent-medicine business by a recent lawsuit in the English courts, wherein one Alabone, the proprietor of a specific, sued one Morton, his former manager, for stealing his ideas and testimonials and setting up an opposition trade. Alabone is an M.D. from Pennsylvania; Morton made no pretence of being a doctor. As has happened before in such cases, the ingredients of the Alabone consumption cure and its bogus nature came out in the trial, as did the qualities of some of the affidavits of cure. Alabone won his suit, but the judge in giving judgment in his favor suggested the propriety of having both the parties prosecuted for infringement of the Apothecaries' Act. The London *Times* suggests that the real victory in the case is with the public, which may profit by the disclosures made in the course of the trial as to the worthlessness of nostrums. But the mainstay of the patent-medicine gentlemen is people who do not concern themselves very much about the law reports. What they want is something to take, and they take that which is offered with the most persistence and recommended in the largest type. However worthless any particular patent medicine may be, it is nobody's business to make that worthlessness public, whereas it is the particular business of the proprietor that the medicine shall be systematically cracked up and put upon the market. The true way to kill off a patent medicine is not to demonstrate that it is of no value, but to invent a new one and advertise it in bigger letters. — *Harper's Weekly.*

# COMMUNICATIONS.

## LATERAL ANASTOMOSIS BY THE MURPHY BUTTON FOR ARTIFICIAL ANUS; RECOVERY.

G. D. THOMAS, M. D., Chicora, Pa.

Mrs. H., white; age 50. The mother of four children, the youngest 13 years old. The husband of this patient called at the office on Friday, Jan. 6, 1893, for something for pain in the bowels. Furnished him appropriate remedies for an attack of intestinal colic. The patient not improving, I was called the next evening (Saturday) to see her and found her suffering extreme pain, located principally in the left umbilical region, with soreness on pressure at the point of greatest pain. The patient was slightly jaundiced and for constipation, the day before had taken a physic with one small stool resulting. The pain was accompanied by tenesmus and occasional vomiting of a bilious nature. Thinking I had an attack of biliary colic to treat, I resorted to proper medication alleviating pain with the hypodermic needle. Saw the patient again on Sunday. Bowels not relieved. Face pinched and jaundiced. Vomiting aggravated and still of a bilious color. Further questioning of patient a history of a "lump" in right groin was reported. An examination of this region modified our diagnosis to that of strangulated femoral hernia of the right side. Taxis failed to relieve her and all medication having proved of no avail, operation was at once decided upon and assistance requested.

The next day, Monday, operation was performed by Dr. R. S. Wallace, of East Brady, assisted by Dr. J. L. Campbell and the writer, both of Chicora. The loop of intestine was soon found but proved very difficult to reduce. Bands of adhesions had firmly united bowel, sac and abdominal walls in one mass. After half an hour's labor by a peeling and snipping process the bowel was returned in a fair condition. All of the sac that could be removed was taken away and the sutures introduced. The patient stood the operation well and started on what seemed an uneventful recovery.

Eight days later a serous discharge appeared from drainage sinus, followed by a rise of temperature, and two days later the sloughing of the sac *en masse*. The sinus continued to discharge but was kept of a serous type by antiseptic injections and dressings. All attempts to heal the sinus proved unavailing. The bowels had a tendency to constipation after the operation, but by careful treatment movements were had almost daily. The patient began moving around the house, the bowels becoming harder to move, till February 21, they failed to respond to treatment. This was soon followed by a milky discharge from the sinus, small in amount. The next day the discharge was more abundant, of a brownish-yellow color, being fluid and floating very little solid matter. We now had a fecal fistula resulting from the stricture of the bowels. The amount discharged from the sinus depended somewhat on the condition of the bowels. When a movement *via naturalis* was obtained the discharge nearly ceased. When the bowels became constipated the discharge was enormous, soaking dressings and bedding in a few minutes. Periods of constipation now alternated with loose bowels for four weeks, when the stricture of bowel being regarded of a permanent nature, a second operation was advised.

The second operation was performed by Dr. R. S. Sutton, of Pittsburgh, assisted by Dr. S. D. Bell, of Butler, and those present at the former operation. A coeliotomy in the *linea alba* was selected and an incision 3½ to 4 inches long made between umbilicus and symphisis pubis. The operation was quickly performed requiring but nineteen minutes from first incision till buttons were introduced. The steps in the operation, after locating the loop of intestine involved, were the same as recommended by Prof. Murphy, of Chicago, in his original article. First, introduction of running stitch "purse string"; second, button-hole incision; third, insertion of buttons; fourth, securing "purse string"; fifth, meeting male and female portions of button.

Although this operation has been performed a number of times in abdominal

work since it was given to the profession in December last, this is believed to be the first use of the buttons for artificial anus. Nothing was done with the old sinus, nor the five to six inches of intestine in each arm of the loop below the insertion of the button. The operation was performed at noon on Saturday March, 25. The patient though much emaciated entered the operation without any fear. She rallied well and as in first operation required no morphine or other agent for pain. Was nauseated from the anæsthetic and was restless through the night, sleeping but little. For three days previous, rectal alimentation had been adopted; this was continued with the addition of brandy.

Sunday 26th. Pulse 98 to 112, temperature 98.6°. An urticaria of entire body appeared that entailed much suffering from its intolerable itching, the patient declaring it would drive her insane if something was not done for her relief. Soda and borax bathing failing to relieve, the patient was anointed with the officinal zinc ointment, to which was added three drachms of chloroform per ounce. The relief was immediate and permanent.

Monday 27th. Pulse 95 to 110, highest temperature 100.4°F. Restless. Rectal alimentation continued and one drachm bovinine every two hours added to the diet, the latter *per orem*.

Tuesday 28th. Pulse 95 to 110, highest temperature 99.6°. Insomnia persisting.

Wednesday 29th. Temperature normal. Oedema of ankles. Urinary examination with negative results. From this on there was no elevation of temperature till April 5th, when a small stitch abscess formed in the line where the sutures had been removed four days before; the stitches all being out on the eighth day. On the seventh day broth was added to the diet by the mouth and rectal feeding resorted to less frequently. The bowels moved sooner than we anticipated, the first movement occurring in the first twenty-four hours. It was small and from the lower bowel only, where the alimentation had been maintained for a number of days. On and after the sixth day bowels moved from above and have continued to do so, the tendency to constipation that the patient has had for years being overcome. The sinus discharged less and less and in three weeks bowel contents ceased to pass from fistula and ten days later the sinus healed. From the first the sinus was treated with peroxide of hydrogen, antiseptic injections and iodoform in injection and dressings. The button seemed to leave its moorings on the fifth day as determined by palpation through the emaciated abdominal walls. The nurses were instructed to be very watchful of dejecta for the button, but it failed to make an appearance to their vigilant eyes.

During the convalescence the patient suffered from an attack of acute articular rheumatism. In fact three attacks; one antedating first operation from which she was just recovering; the second between operations, and the third late in her convalescence. Dating from the appearance of œdema of left ankle she was much troubled with phlegmasia in that limb, extending to Poupart's ligament. Repeated examinations of urine, chemically and microscopically, proved negative results. Coupled with this was a frequent micturition which seemed to be entirely of nervous origin. The hernia that became strangulated was an old one dating back to her third pregnancy, some seventeen years before. It had never occasioned her any inconvenience except the mental one—that there was a lump in her groin that ought not to be there. No truss or other support had ever been applied. Our case that started out as strangulated hernia gave us a varied career, the complications being sloughing of sac, stricture of bowels and an artificial anus, besides having rheumatism, phlegmasia, eczema and urticaria as sequelæ to make up the full program.

The only element short of a perfect recovery at this date is a stiffness of knee joints, superinduced by rheumatism plus her long confinement, plus a semi-upright position maintained by patient despite protestations, her weight being supported by her feet resting on a box foot-rest while she reclined on a toboggan slide made of half a dozen pillows. This however is rapidly improving and the patient can be reported as, recovery perfect.

The advantages claimed by Prof. Murphy were exemplified in our case.

No imperfect application of sutures; no sloughing; no imperfect apposition of openings; pressure uniform; no absorbing of sutures too early; length of opera-

tion minimized and shock the least possible for an operation of this magnitude. We had some concern about the loop of bowel that was "switched off," but up to this date has given us no trouble.

NOTE.—Was called to see Mrs. H., August 11th. Complained of intestinal pain. Followed the next two days by vomiting and purging, the pain continuing but in a mild form. Early on Monday morning, four months and twenty days from operation, the button was passed without trouble *per via naturalis*. Will say patient has continued in excellent health, being robust and going about her household duties. G. D. T.

## INTUBATION WITH REPORT OF CASES.*

G. D. NUTT, M. D., WILLIAMSPORT.

My object in presenting this paper before you to-day, is not so much to record the results of the small number of intubations that have come under my observation, as to bring the subject of pseudo-membraneous laryngitis before this Society, for a full, free and intelligent discussion.

A disease, so prevalent, dangerous and destructive, certainly should call for more consideration at our hands than has been accorded it in the past. In looking over the transactions for the past five or six years, I fail to find any paper or discussion on this subject except a few remarks in a paper read before this society at Harrisburg by J. M. Batten on "The Treatment of Diphtheria."

The absorbing interest in all surgical diseases as obtained by the introduction of aseptic surgery, and the great advancement and success of abdominal work, has had a tendency to divert professional thought from medical subjects, which generally do not yield such brilliant results.

While mothers are being saved from a torturing death or chronic invalidism by rendering them incapable of producing more off-spring, pseudo-membranous croup is claiming those already born with a frightful mortality.

Jacobi in Pepper's System of Medicine says, "Infants and children under two years almost invariably die." "The percentage of average mortality rates from 80 to 90 per cent." Flint says, "Of twenty-two cases analyzed by Dr. Ware, nineteen proved fatal." Dr. Edward Rosenthal stated in a discussion before the Philadelphia Medical Society, "That in a serious of some four hundred and twenty odd cases which he had followed, and studied in his practice and those of his friends, which were not treated by intubation or tracheotomy, but three recovered." Such figures as these, gentlemen, cannot but arrest our attention and make us shudder at the risk our little ones have to endure, in this fatal disease.

Whether all cases of pseudo-membranous laryngitis are from the same cause, and are but different phases of diphtheria, seems to be a disputed point. While many of our best authorities believe that diphtheria and membraneous croup are one and the same disease, arising from the same micro-organism and only differing in degree, and location, more recent investigations tend to prove that they arise from different bacteria and thus form two distinct and separate diseases.

From a close observation and careful study of the clinical history of diphtheria, and membranous croup, covering a period of twenty-three years and including many hundred cases, I have frequently noted many different phases of the deposit, so much so, that I have long believed we have three distinct varieties or types of membranous formation liable to invade the larynx, differing widely in the character of the deposit, mode, and location of invasion, and results.

In the regular or common form of diphtheria, the disease commences with a high fever, considerable constitutional disturbance, and a membranous deposit of a thick greyish-white, which rapidly forms and spreads over the tonsils, with a tendency to invade the soft palate, nasal passages, or downward to the vocal cords, and larynx. If arrested it soon separates, coming off in thick leathery patches, quite offensive, and very contagious. When severe,

* Read before Penna. State Medical Society, 1893.

the sub-mucous cellular tissue and glands of the neck become infiltrated with the poison, swell, and soon contaminate the system. These cases usually are followed by some form of paralysis. If it invades the larynx it is usually in the latter stage of the disease when the patient has become weak and debilitated; and is in a poor condition for either the employment of tracheotomy or intubation. Consequently the rate of mortality is very high.

There is another form of diphtheria differing from the above in many important features. The invasion presents about the same symptoms, but the membrane is thin and remarkably white in color, rarely has any odor and very little glandular involvement. It spreads over tonsils, pharynx, soft palate and larynx. It is very firmly attached to the mucous membrane, and is slow to separate. It seems to wear off or absorb, rather than become detached. It yields more slowly to the effect of mercurials than the previous form, but does not weaken the patient so much or so rapidly, although the regular paralysis usually follows. Its tendency to invade the larynx, is in marked contrast to the previous form.

In this form it is not unusual for the false membrane to remain on the tonsil or some portion of the mucous membrane two or even three weeks. In one child that had to be intubated, the tube was left in fourteen days before the last vestige of the membrane disappeared.

The third type is the membranous croup of the old writers. It occurs in isolated cases, with but little constitutional disturbance except symptoms of cold and hoarseness. It always invades the larynx and trachea and is never seen above the vocal cords except in small isolated patches. To the naked eye the membrane cannot be distinguished from other forms of diphtheria. It yields readily to mercurials if the system is brought under its influence early. Its contagiousness is very doubtful. It usually attacks only one member of the family and is rarely associated with other forms of diphtheria. Although very fatal, it generally causes death by its mechanical effect. Consequently the results of intubation in these cases are very satisfactory, and yield a good percentage of recoveries if properly managed.

Although the clinical histories of these three forms or types of diphtheria seem so different in their nature and formation as to strongly suggest a different micro-organism, yet practically, the treatment is the same. My observation accords with many others in the value of the mercurial form of treatment, but to insure its effect it must be given early, and in frequently repeated doses, so as to insure its rapid physiological effect. By this treatment the disease is arrested, and the false membrane soon separates or becomes dead.

When the larynx becomes involved its mechanical effect becomes an important factor in the successful management of the case; and whether we should perform tracheotomy, or intubation, and *when*, is a question of vital importance.

My own experience is decidedly in favor of intubation if performed early. Just as soon as the obstructed breathing, and prolonged expiration show that the lungs cannot perform their proper function.

I have performed *tracheotomy* several times for membranous croup but the results have never proven satisfactory. True it was not used until death seemed imminent; but one of the most serious objections to its use, is the inability to obtain the consent of parents and friends before the danger point is reached. It is not only a tedious and bloody operation, but the care that has to be excerised in the after management of the case is a serious obstacle to its success in general practice.

It is not to be supposed that placing a tube in a child's throat alone is going to save our patient. It simly overcomes the mechanical obstruction to breathing, providing the membrane has not extended too far in the trachea; and prevents death from suffocation, thus giving us more time for its future treatment. The subsequent management of the case requires good care, and such modifications of our remedies as the presence of the tube requires.

A warm room heavily loaded with moisture, and the frequent inhalation of steam from slacked lime, are essential to the success of the case. The continuance of the mercurial treatment can best be carried out by allowing the child to inhale the fumes arising from burned calomel.

The proper feeding of the patient is one of the most objectionable features of intubation.

Very little if any liquid should be given by the mouth during the first twelve hours. If the patient is very weak use rectal injections. If necessary, however, to excite cough, in order to expel accumulated mucus, an occasional sip of water may be given. After that period either boiled milk, or lime water and milk, may be given at intervals, while the child is lying on its back with head very low as recommended by O'Dwyer, either in spooonful doses or sucked through a tube or nipple. Any soft, semi-solid substance that has no lumps or hard particles, can be given. Such as corn starch, junket, cup custard and the like.

The patient requires constant watching, especially if the string is allowed to remain in the tube, Eternal vigilance is the price of success.

During a discussion of membranous croup before the Philadelphia County Medical Society about a year ago, I made the remark, that I had had at that time seventeen *consecutive* cases of intubation with only four deaths. I did not mean that was my percentage of recoveries.

When I first began to use the tubes some five or six years ago, the first three cases intubated all died; but the tubes were not introduced until the last moment, when the patients showed decided symptoms of suffocation, by blue lips and tips of fingers, congested lungs, and weak, thready pulse. Although relief was obtained for a time, death soon followed from congestion of the lungs.

The next six cases were intubated in a much earlier stage of the disease and all recovered; followed by eleven more cases with only four deaths. Since that time the percentage of recoveries has not been so good; due in a great measure to the class intubated. During the past year a large percentage of the cases has been of a severe diphtheritic type. I have not hesitated to use the tubes even in apparently hopeless cases if there was a likelihood of giving relief.

In giving a tabulated statement of all the cases intubated up to date, I have for convience and comparison divided them into diphthertic and membranous croup.

The whole number intubated has been forty-four. Recoveries twenty-five, deaths nineteen. Of these, twenty-three cases were diphtheritic croup, with ten recoveries, and thirteen deaths. Twenty-one cases of membranous croup, with fifteen recoveries, and six deaths.

There were eight children under two years of age, with two recoveries, and six deaths. There were fifteen between the ages of two and five years, with six recoveries, and nine deaths. While there were twenty-one five years old and over, with seventeen recoveries, and four deaths. The youngest child was eight months, and the oldest ten years old.

In three cases that died of diphtheritic croup, the croupy symptoms were relieved, and the tube removed, but death occurred later from the systemic poisoning. In a number of cases the membrane was detached at the first insertion of the tube, and in three of these, the tube was never re-inserted; the patients making good recoveries. In one case, as I have mentioned before, the tube remained in fourteen days; the usual length of time being four or five days. In no case was intubation resorted to without there being a deposit in the throat or larynx. If not seen, some portion of the membrane was detached and expectorated when the tube was inserted.

These figures if they prove anything, go to show:—

First. That we have in intubation a most valuable and safe method of lessening the mortality of this fatal disease.

Second. That in all forms of membranous croup, in children under two years old, the mortality is very high but by intubation and careful management we may save some.

Third. That in those between the ages of two and five years, we may reasonably except from 25 to 30 per cent of recoveries.

Fourth. In those that are five years old and over, a large percentage will recover, ranging anywhere from 50 to 75 per cent.

---

**He was Exposed to Success.**

Rosevelt—When Bloomstein was in the hospital with us, you remember, we used to consider him stupid. How did he manage to build up such a large and remunerative practice?

Hannemann--He was just shrewd enough to establish himself in a town where the local paper published a column of medical advice each week.—*Puck.*

# OSTEO MYELITIS*

O. WELLINGTON ARCHIBALD, M. D., Jamestown, Md.

J. C. H.,aged 24, Sykeston,N. D. Some 12 years ago patient fell on frozen ground somewhere in Canada, injuring left leg; says attending physician afterward removed 32 pieces of bone from limb. From that time until he came under the notice of Dr. Cooke during the latter part of December, 1892, had no pain in limb with exception of winter of 1886, at which time, pain described as of dull and aching character lasted several weeks. With that exception limb had seemed perfectly strong and health during the 12 years was good.

When first examined a very noticable enlargement was found over crest and anterior surface of tibia, about the middle, somewhat more reddened than parts adjacent and slightly sensitive to pressure. Patient complained of excruciating, boring pains, greatly intensified at nights and constantly increasing in severity, and diagnosis of periostitis, or osteomyelitis was made and the probable necessity for early operation explained to patient. I directed poultice to be applied at night and tincture of iodine several times during each day. Impossible to secure sleep at night with any kind or reasonable quantity of drugs. About the middle of January, exploratory incision was made the result of which was entirely negative. Some relief followed for several days, after which pains recurred with increasing severity. Osteo-myelitis was determined upon as cause of trouble and patient came to Jamestown for operation. Upon arriving there an operation was made consisting of an incision some 6 inches in length, which resulted in exposing 2 areas of necrosis opposite each other about centre of bone, upon external and internal surfaces, with sinuses running down towards center, from which considerable pus escaped. The establishment of drainage resulted in complete relief, the two openings were packed with gauze tents and patient returned home a week after, with prognosis of probable amputation in near future. After about 3 weeks, during which time I was in correspondence with Dr. Cooke in whose practice the case occured, another and more radical operation was determined upon and performed on Feb. 17th, with the assistance of Drs. Cooke and Moore.

When etherized, the limb was rendered bloodless by use of Esmarch bandage, and tourniquet applied above knee. An incision 8 inches in length was made down centre of anterior surface of tibia, and the flesh together with the periosteum carefully dissected up so as to expose the entire width of bone. Numerous foci of necrosis were found upon surface, and periosteum entirely gone in some places, leaving surfaces of bone rough and pitted. Beginning at upper angle of incision the trephine was applied at four points at intervals of about one inch, the instrument being carried well down to center of bone. The intervening bridges of bone were then removed with mallet and chisel and whole interior of bone for some 6 or 7 inches thoroughly scraped with Volkmann spoon.

A number of pockets containing from a few drops to several drachms of pus were found. Running off from lowest trephine well down to within one and one one-half inches of ankle joint was a cavity 2 inches in length containing fully one-half ounce of pus, the walls of which, after removal of pus and thorough scraping, were found to consist merely of outside,cancellous tissue—to be simply a shell, in fact. Copious bichloride irrigation was used throughout operation and great care exercised to remove every particle of necrotic matter. After careful cleansing and irrigation the wound was tightlypacked with Senn's decalcified bone chips and periosteum and flesh sutured with cat-gut, leaving an opening of about one inch in length at center where approximation was impossible, due to result of former operation; wound dressed anti-septically and patient put to bed. Time of operation one hour and 15 minutes. The wound healed throughout by first intention and patient returned home ten days after. Result, perfect recovery.

*Read before North Dakota Medical Society, 1893.

# MOVABLE KIDNEY AND SOME NERVOUS AND OTHER SYMPTOMS ARISING FROM IT.*

SAMUEL AYERS, M. D., PITTSBURG.

Mr. President: The subject of Movable Kidney has not, I think, received that consideration which its importance demands,—and for several reasons.

First. Though Rayer, as early as 1839, brought the matter clinically before the attention of the profession, it is only within recent years that extended studies have been made in this direction; and therefore a knowledge of the subject has not been widely diffused.

Second. The region of the kidney has been generally regarded as terra incognita, almost beyond the hope of exploration, and the organ itself as too inaccessable for direct examination, and

Third. Until the present improved operation for nephrorrhaphy had been devised, nearly all means for the relief of displaced kidney were unavailing.

Hence it is not strange that the body of the profession has been slow to realize the frequency and the importance of the trouble.

Thanks to the efforts of such men as Lindner, Landau, Keen, Litten, Edebohls, Keppler, Scmitt, Newman, Hahn and others, we are in possession of an extensive and valuable literature, and the operation for nephrorrhaphy as now practiced is one of the most important and successful in the field of surgical procedure.

Movable kidney is of much more frequent occurence than was generally supposed by earlier writers, doubtless because it was then not often sought for. Newman quotes 11,000 autopsies in which only 11 cases were found, and Skorszewsky discovered only 32 cases in 1,030 women.[1] But Edebohls, who has recently made a valuable contribution to the subject[2] states that in an examination of 500 women, he found the kidney movable generally on the right side, in 90, or 18 per cent. Lindner discovered the same abnormal condition in one out of every five or six women examined by him.

By movable kidney is here meant the organ freely movable within or out of its fatty capsule for a distance of from two to eight inches or more from its normal position. This is differentiated from the so-called floating kidney, which is generally congenital, and within the peritoneal cavity, having a mesonephron formed by a reduplication of peritoneum. Notwithstanding this distinction, it is probable that both the movable and floating kidney are attended by similar symptoms.

If we begin with the proposition which is indeed quite axiomatic, that a prolapsed organ, no matter where it be, is liable to create mischief and to be a source of pain or discomfort, we shall at once appreciate the harm that may result from a movable kidney. The traction upon the renal nerve and vessels, the general dragging upon the sympathetic nerves and their ganglia, the reflex irritation thus excited, the undue pressure of the displaced organ, on the bowel or other parts with which it may be in contact are quite enough to create extensive disturbances in the economy. Then again, as has happened, if the kidney becomes incarcerated or twisted so that the circulation or outflow be obstructed, hydronephrosis may supervene and the life of the patient be imperiled.

Since movable kidney has been so infrequently recognized until recently, and is perhaps now often overlooked, and since as above stated, its presence is usually attended by symptoms both persistent and distressing, it is reasonable to infer that the liver, but especially the pelvic organs have been often unjustly accused; for some organ or structures had to be saddled with the symptoms, and what more natural than to hold the much abused generative organs responsible.

However, there are some extenuating circumstances in cases in which this error has been committed, for the effects of a displaced kidney closely resemble those of pelvic disease, and can often be differentiated only by the results of operation. Edebohls in some of his cases, which

* Read before Penna. State Medical Society, 1893.

1 Diseases of the Kidney, Morris, p. 27.

2 American Journal of the Medical Sciences, Vol. 105, Nos. 3 and 4.

were complicated with various uterine lesions, operated only on these, and found that after the lapse of sufficient time, most of the symptoms persisted, but that after the fixation of the kidney by suture the patient generally recovered, thus proving the dependence of the trouble on the movable kidney.

It must be food for serious reflection to many gynecologists, that after operating successfully on different diseased pelvic organs, including the rectum, they have failed to relieve the patient, who persists in her chronic invalidism, and in the complaint of dragging lumbar pains, and side aches, backache, dyspnœa and dyspepsia, which it had been promised would disappear after the operation. A displaced kidney has been overlooked, and the result is, a failure. The patient is called hysterical, and all sympathy and further assistance denied her. The moral is brief and emphatic—in every investigation of the pelvic or abdominal organs, the position of the kidney should be carefully ascertained.

During the past year I have seen six cases of movable kidney in women, four among my private patients, and two through the courtesy of Dr. Werder, who has kindly permitted this reference to them. In four of these cases, the right kidney only was movable, in two, both organs. In only one of them, a case of Dr. Werder's, has nephrorrhaphy been done, which proved entirely successful. In one of my cases, both kidneys being very movable, the woman had consented sometime ago to operation, but an intercurrent disorder has postponed it.

The symptoms of this abnormal condition are quite marked, and even uniform, as I have observed them and as detailed by other writers. Edebohls, in the paper above referred to, summarizes six leading symptoms in uncompliated cases, which I here quote, "Digestive disturbance, chronic in character, general nervousness, epigastric pain, usually located somewhat to the left of the median line, at or near the free border of the left costal cartilages, cardiac palpitation, inability to feel comfortable or to sleep on left side." In addition to these symptoms, I have noted decideds pinal pain in one case, referred to me as "spinal irritation," great dragging and aching and sense of weight just below the free border of the ribs on the side corresponding to the prolapsed kidney, coccygodynia in one case, severe periodical attacks of pain in the region of the kidney, in one case, which I formerly took to be uncomplicated lumbo-abdominal neuralgia from unknown cause, periods of mental depression, a sense of great fatigue and tire in the lower extremities after the least exertion. Two of my cases had all the stigmata of so-called "nervous prostration," and this has lead me to seriously inquire whether this trouble may not often be the chief cause of some cases of neurasthenia in both men and women.

Dyspeptic troubles were present in all my cases, and of a very obstinate character; also constipation, whether produced by the pressure of the kidney on the duodenum as alleged by some, or whether from the general disturbances of nutrition.

The causes of movable kidney are yet somewhat in doubt. Some writers think it chiefly due to the absorption of perirenal fat, which seems a very plausible theory, though Keen states that in some of his cases the normal amount of adipose tissue still remained. Traumatisms from falls, strains, etc., are also doubtless leading factors in the etiology. Lean persons with lax abdominal walls, and child-bearing are potent predisposing causes. In one of my cases the trouble dated from an attack of typhoid fever, and was much aggravated by a fall some years later.

The diagnosis of this condition is not difficult if the physician will but remember to make a careful examination, and this is usually easy, since movable kidney is commonly found in thin women, with little resistance of the abdominal walls. The method I have pursued is to place the patient upon an operating chair, the plane of which shall be about thirty degrees from the horizontal. The patient lying supine, with legs flexed, the mobile kidney will slightly descend by gravity from its normal position; then by deep upward pressure from behind just below the border of the last rib with the fingers of the left hand, if examining the right kidney, and counter pressure over the front and side of the abdomen, just opposite, there will be little difficulty in outlining the organ, and noting its size and mobility.

Occasionally the kidney will slip up so high under the liver that it cannot be easily dislodged. If the patient now be

instructed to deeply inspire, and hold her breath a moment, the kidney will descend and may be felt to slip back between the fingers of the two hands during expiration or by slightly relaxing the pressure.

The size of the organ and its mobility can usually be quite clearly made out. Some writers advise for the examination that the patient sit on the edge of a chair, leaning forward, with the hands resting on her knees, but I have never had occasion to try this method.

The prognosis of movable kidney is quite unfavorable without operative interference, indeed the organ is perhaps never securely held in position by any plan of treatment save surgical. Temporary benefit by belts, compresses or pads may be obtained, but such measures are extremely disappointing.

If one will firmly compress the loose kidney with the hand, the very best of all supports, while the patient stands erect, and note the facility with which an inspiratory effort will force it from under his grasp, the futility of all ordinary appliances for this purpose becomes at once apparent.

Nephrorrhaphy or the fixation by suture of the kidney to the abdominal wall offers the only permanent relief. This operation as now performed is followed by a mortality of less than three per cent., and by a percentage of recoveries from symptoms varying from sixty to ninety.

In the excellent paper of Dr. Keen,[1] read before the American Surgical Association in 1890, 134 cases are reported as having been operated on by different surgeons, with four deaths. And no more forcible argument could be advanced in favor of nephrorrhaphy in properly selected cases, than that suggested by Keen's 4th case there reported, the patiet being a physician.

But it is strongly advised here that this operation be not hastily or rashly undertaken. A movable kidney is not equally disturbing to all who have it. My friend, Dr. Stewart, of Pittsburgh, recently told me that he found such a kidney in one of his patients who had no symptoms whatever resulting from it, and I have heard of other similar cases. Just as there may be no ill effects from uterine lesions in some women, so there may be no manifestations from a movable kidney. This, though, is doubtless exceptional, and we have good ground for stating that in women and men of nervous temperament, this abnormal mobility of the organ is a leading factor, if not the chief one, in the production of many nervous and painful phenomena.

It is further suggested that where this trouble is complicated with various pelvic lesions, these be first cured and sufficient time allowed to estimate whether the movable kidney is the disturbing agent. In one of my patients who had besides a movable kidney, endometritis, laceration of cervix and perineum, rectocele and hemorrhoids, these last have all been recently repared in order to determine this point.

It is not the purpose of this paper to enter into the details or methods of the operation for nephrorrhaphy. These can be obtained from the most recent surgical works and journal articles, nor does the paper claim to be a contribution to the literature of this important subject. Its aim is to bring the matter again before the attention of the profession; to advise a more careful investigation into the symptoms heretofore attributed too exclusively to disorders of the sexual apparatus; to urge a more thorough examination of the kidney in every case, and the performance of nephrorrhaphy as soon as it is positively determined that the symptoms are serious, that the loose kidney is the offending organ and that other measures of relief have proven fruitless.

1 Transactions of the American Surgical Association, Vol. 8, 1890, p. 181.

### Vaseline as a Lubricator.

Novotny Memorabilien warns against the use of vaseline as a lubricator for sounds and other instruments introduced into the bladder, as he has twice found this substance left behind in the bladder, serving as a nidus about which a mass of detritus had collected, and giving opportunity for the deposit of urinary sediments. In one case the quantity thus massed together upon a quantity of vaseline weighed ten grains.

Sodium Bisulphite is reported to produce excellent results in tonsillitis and coryza. Tablespoonful doses of a satuated solution are given every hour or two for twenty-four hours, or longer if necessary, the disease being usually controlled in twenty-four hours.

# DIARRHŒA IN CHILDREN.*

J. D. WEAVER, Norristown, Pa.

ETIOLOGY.

Logically I feel that I must begin with the *constitution.* A child born with a vice is so liable to take on a fatal form of diarrhœa in summer that we dread the approach of the heated term. Therefore, if I were going to blot out this trouble, I would begin with the parents, and allow only the sound in body, mind and soul to marry.

2. *Surroundings* have much to do with running out the light of the little one through its alimentary canal. Filthy and heated apartments, coupled with poverty, certainly lower the vital powers to an alarming extent.

3. *Age.* Holt gives in his table the greatest frequency in the second six months. A record of 772 cases shows:

| | |
|---|---|
| 1st six months | 119 cases |
| 2nd " " | 237 " |
| 3rd " " | 149 " |
| 4th " " | 125 " |
| Over two years | 142 " |

4. *Dentition.* It is possible that in certain cases and at certain times this is a factor in producing diarrhœa; but not often enough for any of us to dismiss an anxious mother with the words, "Oh, it is only teething, and it will not do to stop the diarrhœa at once." Never allow the laity to neglect a diarrhœa.

5. Brings us to one of the great factors, *diet* and *feeding.* Of 1942 fatal cases recorded by Hope and others, 97 per cent. were bottle-fed. I do not remember loosing a single case of diarrhœa that was fed exclusively from the breast. These facts, then, are certainly alarming and it behooves us to make a greater effort to have our girls so trained physically that when they become mothers they shall be able to perform the duties of maternity.

Why is artificial feeding so dangerous in summer? How many cases of diarrhœa have any of us treated this last winter, known as the coldest for many years? None worth mentioning, and these can be accounted for other than by feeding. It cannot be due to the chemical composition of the milk else our babies would fail in winter as well as in summer. Nor is it wholly due to improper or overfeeding, although I am compelled to admit that over-feeding, irregular and too-frequent feeding and the habitual use of improper food, all unite in producing infantile indigestion; and this dyspepsia is a predisposing cause of diarrhœa. But these evils exist in winter as in summer, so my query as to why artificial food is so dangerous in summer is still unanswered. Since diarrhœal diseases occur with greatest frequency in summer, and with exactly the same conditions except high temperature, rarely or not at all in winter, one would naturally suppose that the heat is the important factor. It is true that heat so lowers the vital forces that the usual amount of food, of whatever kind, cannot be digested with the same vigor, but I firmly believe if the food were decreased two-thirds and the hygienic surroundings were in keeping, that the majority of cases of indigestion and diarrhœa could be avoided. We are struck with the fact that the greatest mortality occurs in the first few weeks of continued hot weather, while we would suppose, if high temperature were the sole cause, the last month when the temperature is highest would present the greatest mortality. Holt thinks the reason why July records greater mortality than August is that a certain number of children are born to die. In other words the weaklings succumb; the strong are left and able to withstand the telluric changes. While this is no doubt true, I would add that in August the doctor and laity are more alert and greater care and precautions are taken to preserve a higher standard of health. Dr. Seibert of New York, has studied every summer month for ten years, separately, as to maximum and minimum temperature and relation of these to the prevalence and mortality of diarrhœa. These observations, which I will not here recount, show conclusively that there is no constant relation between the degree of heat and amount of diarrhœa, and consequently heat is not the direct agent that produces diarrhœa.

We now come to the chief causative factor which we believe to be *bacteria,* a certain degree of atmospheric heat and

* Read before the Montgomery County Medical Society, 1893.

artificial feeding being necessary conditions in their formation. Summer heat brings forth a micro-organism that grows and multiplies. In fact its procreative powers are so great that it is not in the mind of man to compute the offspring of a pair for one week, let alone a summer. These live, grow and multiply in artificial food and to this germ we must look for the cause of the great danger of artificial food in summer. The hot season is the one for rapid growth, maturity and decay in the vegetable kingdom, to which most of the specific causes of disease known belong.

PROPHYLAXIS

Having a definite conception of the causes of summer complaint, the prevention is simple, providing the laity will follow instructions.

1. Watch children with a vice; support and build up as best we can.

2. Let the sanitary surroundings be the best that can be provided. House rent is dear, air cheap. If it is a home of poverty persuade the mother to take up her dirty old rag carpet during the summer months and keep the house clean and sweet. I saw an ideal sanitary home the other day—an Italian's. Not a particle of unnecessary furniture, no hangings, no carpets. From cellar to garret as clean as a new pin. Children dressed in a single garment. Everything looked cool and comfortable.

3. Give careful instruction on *foods and feeding*. Ignorance here is fatal. Of course, we will urge every mother to nurse her child at her breast. I have not in all my cases this summer been called to see a child suffering from diarrhœa that was nursed exclusively at the breast. Learn and teach the capacity of a child's stomach; there is not the least danger of feeding too little. Be careful of too frequent feeding. Especially at night I would recommend the latter.

Outside of cow's milk, the physician should exercise great care and judgment if he allow any other kind of food for an infant under two years. "One man's meat is another man's poison," is true also of babies. We are at times compelled to try other than the staple articles of diet, but in all such cases the reason should be clearly given that this particular food is only allowable for this condition. By all milk is considered the chief article of diet, and is the universal food in artificial feeding. Let us get it to the consumer in as perfect a condition as possible. If it is the microbe in the milk that causes indigestion and diarrhœa, let us kill the animal. An enterprising worker found two hours after milking, in 16 drops of milk examined 9,000 bacteria, in an hour more 31,700, and 25 hours after 5,000,000 had developed. As there seems to be no doubt that cholera, typhoid fever, diphtheria, scarlet fever, and diarrhœal diseases are contracted and disseminated from contaminated milk and water, I would suggest that we get our milk from a dairy near at hand so it need not be handled often, nor heated by long exposure in transportation. The dairyman should not feed his cows brewery and deleterious slops, but should keep them in good pasture lands, and in clean and well ventilated stables. See that they get good food and pure water to drink. The milkers should have clean hands, and wash the udders at each milking. They will also see that the vessels are clean and sweet. The milk should be kept at a temperature of fifty degrees till delivered to the consumer. Having the milk properly delivered at the home, it should not be allowed to stand in pitchers, etc., but should at once be boiled. Endeavor before feeding (by taking from and adding to) to bring cow's as near as possible to the chemical composition of mother's milk. Without entering into details of diet for infants, I give a practicable formula from *Annals of Hygiene*: Boil milk, skim off top film (serum albumen), add ten per cent. lime water, twenty-five per cent. boiled water (more or less according to age of child), and thirty grains lactose to each ounce. Should be kept in air-tight bottles or earthen vessels that can be made air-tight, placed on ice and used as needed. By these means you have sterilized milk which cannot sour. You have removed the indigestible serum albumen, increased lime salts, sugar, and water to human milk standard. If we remember that during the first four weeks an infant requires twelve to sixteen ounces of food in twenty-four hours, at two and three months old from twenty to twenty-four ounces, and so on, we are not likely to overfeed. I think very often a child is overfed because the mother is ignorant as to size of organ she is so anx-

ious to fill and glut. At birth the stomach resembles my thumb as much as anything I know of, and holds five drachms; a week old seven drachms, and increases in size in ratio of one for first week, two and a half for the fourth, and so on.

To sum up, prophylaxis demands of us:

1. Care as to surroundings.

2. The education of the laity up to importance of regularity in feeding, dangers of over-feeding and as to proper diet of infants just weaned.

3. Proper restrictions on transportation and sale of milk.

4. The destruction of germs in all foods given, especially milk, by sterilizing, and cleanliness in care of bottles, nipples, etc.

5. Prompt attention to all mild derangements, especially in summer.

6. Lessening amount of food, and increasing amount of pure water during periods of excessive heat.

---

## INTRA-UTERINE ASPHYXIA WITH REPORT OF THREE CASES.*

GEO. F. HULBERT, M. D., St. Louis, Mo.

To those who have had the experience of believing and declaring that the child in utero was living and that everything was all right and looked forward to a happy termination of the parturition then in hand, may possibly from time to time realize the chagrin and sense of defeat when upon the birth the child has been found to be practically dead, yet not dead for the heart still beats with a strong but slow pulsation. Every effort at resuscitation is resorted to; you are cognizant of the fact of air penetrating and distending the alveolar spaces, evidenced by the increased vigor and rapidity of the heart pulsations; and yet in spite of that, after long continued effort, we gradually see slip through our hands the remaining spark of life and the child is in fact dead. It having been my good fortune or misfortune to have three experiences of this character occurring in my obstetrical work, I have deemed it possibly of interest and hope it will be of some value and satisfaction to those who have had or may have experiences of this kind, to peruse these cases and draw their deductions therefrom.

A similarity of circumstances and conditions appertaining to the child as well as to the mother and the character of the labors, and the fact that the normal limits were not apparently encroached upon in any respect, as well as the fact of the peculiar condition briefly detailed above, has emboldened me to call attention to the conditions and to place on record these cases, not that they are especially new or not, but that many others may have had the same or like experience, yet the fact remains that the literature does not abound with information or anything specially calling attention to the class of cases under consideration.

The first case was delivered in a perfectly natural way by natural force; the two subsequent ones were made instrumental deliveries advisedly, simply for the reason that he felt the possibility of a repetition. In all of them he was certain and positive that he heard the fœtal heart not longer than one-half hour before delivery was accomplished; heard it distinctly but somewhat weakened in its force. At the time of delivery in all, the appearance presented by the children as they came through the vulva was one of extreme pallor, with slight if any evidence of cyanosis save a deepened tinge of the lips, with absolute muscular relaxation; there being apparently no response on the part of the muscles to any irritation that might be made. The heart was pulsating at the rate of from 40 to 50 per minute. The usual methods of artificial respiration were resorted to in all, to the extent of introducing the catheter into the trachea and thereby insuring a passage of air into the bronchial tree and alveolar spaces.

*Abstract of paper read before Am. Association of Obstetricians and Gynecologists, at Detroit, June, 1893.

That the air did penetrate was further evidenced by the slight crepitus easily heard during compression of the chest in the expiratory parts of the respiratory act. Artificial respiration was maintained until the heart ceased beating; until it ceased to respond to the stimulus presented by the aeration of the blood by the artificial respiration. In none of them were there any external evidences of pathological conditions, development having been well accomplished. The umbilical cords were not without the normal limits and it was only when the placenta was reached that there were any conditions present that might possibly account for the peculiar condition of the children. Here in all three cases were there found blood clots occupying the placental surface in over half of its area. These clots were well formed, intimately attached to the placental tissue; smooth upon the uterine side. There was nothing indicating the fact that the clot had been torn from the uterine surface, but rather that placental separation had taken place and the clot had formed and become adherent to the placental tissue. So far as the mothers were concerned, they were in average good health; the first a primipara, the last two multipara. The character of labor was not over twelve hours duration and presenting nothing especially attracting attention outside of the fact that the first was one of those cases which might be termed "piston-rod" form of delivery, in that the head was forced down to the peritoneum at each pain, and upon the disappearance of the pain promptly receded to the brim. This was frequently repeated, so much so that he seriously contemplated applying the forceps, and regrets that he did not in order to enable the head to catch beneath the symphysis. The character of the pains were not sustained and vigorous in any of them, but rather more short and inefficient. In none of these cases was chloroform used and in only one, the first, a rectal injection of twenty grains of chloral given during the first stage. The element of compression upon the head was not at all excessive and would not have attracted attention. In the last two cases there was no pulsation appreciable in the cord; in the first case there was no record of this fact. The children were separated from the mothers immediately, and in the first a small amount of blood was permitted to flow through the severed end of the cord. Unfortunately in none of them did he obtain a post-mortem, and as before stated, the only anatomical lesion that he could testify to is the presence of the blood clot occupying an extensive part of the area of the placental surface. There was only a moderate amount of the amniotic fluid following the birth of each child. In the first two cases dilatation was well advanced before the membranes ruptured; in the last case rupture occurred at the beginning of dilatation. The points for consideration are:

(*a*) The presence of the fœtal heart pulsations so soon before delivery.

(*b*) The normal character of the labor.

(*c*) The extreme pallor and relaxation of the child at birth.

(*d*) The presence of the cardiac pulsation after delivery.

(*e*) The absence of any attempt upon the part of the child to perform the respiratory act.

(*f*) The response upon the part of the heart to the benefits of accomplished artificial respiration.

(*g*) The anatomical conditions presented by the placenta.

---

**Pneumotomy in Abscess of the Lung.**

J. J. Matignon, of Bordeaux, has made some observations upon a case of pneumotomy for abscess of the lung, which are of practical interest.

He describes the condition of a young man who kept on wet clothes, after falling into the water while perspiring, in July, 1889. The patient felt a distinct chill while in the water, and a week after this exposure he was attacked with a stitch in his right side and had fever. Frequent relapses occurred from imprudence on his part. Aspiration of the chest was resorted to, with injection of eucalyptus-oil. On January 27, 1891, Baudrimont performed pneumotomy for a abscess of the lung. The cavity was washed out with a solution of boric acid, and powdered iodoform was dusted into it. The wound was dressed with gauze and a bandage. Six months later the patient was examined and declared to be well.—*Journal de Medecine de Bordeaux.*

# SOCIETY REPORTS.

## THE LOUISVILLE MEDICO-CHIRURGICAL SOCIETY.

*Stated Meeting July 21, 1893.*

### MYOMA OF UTERUS; OPERATION; RECOVERY.

DR. A. SCHACHNER (Visiting): Myoma of the uterus removed from a patient thirty-five years of age. She has had this growth, her physician, Dr. Beckels, tells me for about three years. The adhesions were confined to the posterior portion of the tumor. The growth was removed and the pedicle treated extra-peritoneally. The patient made a very nice recovery. I am under obligations to Dr. Cecil for assisting me in this operation. For the first few days the bowels were a little troublesome and obstinate, but this feature was finally overcome by high enemas of fresh ox gall. The stomach was in such a condition that it would not retain any of the salines. Several purgatives were administered hypodermatically which did not seem to have any effect. High injections of ox gall with some sulphate of magnesia finally relieved the bowels, and from that time on she had no further trouble. The uterus weighs two pounds.

### MULTIPLE CYST OF OVARY—OPERATION—RECOVERY.

This tumor I diagnosed as one of the uterus, but proved to be a tumor of the ovary, and I judge it to be a multiple cyst. The reason I took it to be a myoma or fibroma of the uterus was that the clinical history pointed to this conclusion. The patient had uterine hemorrhages, and the position and manner in which it fixed the uterus all led me to believe that it was a myoma or fibroma of the uterus, and I gave this as my opinion, and was supported in this by others who had also seen the case. The tumor while in position was very firm, and so firm that the attending physician had questioned the propriety of removal, thinking that there were too many adhesions which would contra-indicate this procedure. I suggested, however, that as the patient was a middle aged woman that an exploratory incision should be made at least to see what the real condition was, and if it proved as extensive as it seemed to be before the incision, the operation might then be abandoned without any practical risks to the patient. A medium incision was made and I passed my hand into the abdominal cavity and down underneath the tumor to try and determine whether there were many intestinal adhesions; this created such a hemorrhage that I concluded we had better push the operation to a close. I enlarged the incision which ran almost to the ensiform cartilage, and fortunately found no adhesions posteriorly; there was a band which anchored it to the abdominal wall $1\frac{1}{2}$ inches in width and $\frac{1}{2}$ to $\frac{3}{4}$ of an inch in thickness; also quite extensive omental adhesions in which the omental vessels were as large as my little finger. The adhesions were very readily separated and the tumor taken away. From the time the incision was made until I commenced suturing occupied thirty minutes, and from the beginning of the suturing until the operation was completed occupied eighteen minutes, making forty-eight minutes altogether in removal of the tumor. The woman has had absolutely no unfavorable symptom. It is the only laparotomy of this character I have ever seen where the patient never vomited even once; she had some little nausea about the third day. I gave her a whole bottle of citrate of magnesia at one dose; this was very effective and produced such coliky pains that morphine, $\frac{1}{8}$ grain, had to be administered. Sutures were removed on the fifth day and the wound had united throughout to the pedicle by first intention. The pedicle of this tumor was also treated extra-peritoneally. It was drawn out, the peritoneum was stitched around it with silk, the pedicle was ligated with silk and hysterectomy pins placed in the stump for support. It is now almost two weeks since the operation and I think I can safely say that recovery is assured. I saw her last night and the case seems to be running a perfectly normal course, and the pedicle, which is entirely without

the peritoneal cavity, is commencing to give way nicely, so I can safely call it a recovery. The tumor weighs fourteen pounds. Several physicians saw the case before the operation and estimated that the tumor would weigh about twenty-five pounds; I estimated it at twenty pounds, and the result shows how deceptive these growths are. We often read of one-hundred pound tumors, but I think in many instances this is an exaggeration. I mean to say that one-hundred pound tumors of the abdominal cavity are an extreme rarity. I believe they are very much oftener reported than they really exist.

I have a case now which is being prepared for operation, in which I do not think the tumor will reach seventy-five pounds, and if it reaches sixty-five pounds I will be a little surprised. I first made a diagnosis in this case of unilocular cyst, but I will say that several gentlemen had seen the patient before me and they all made the same diagnosis. I say this with no discredit to them, as the woman would not submit to a thorough examination. The examination being made through a thin wrapper and only by palpation, and she refused operation until her condition reached such a desperate stage, that she finally consented on the bare chance she still had of recovery. I had her removed to the Infirmary, taking about two and one-half hours to get her there, and made a small incision when a large mass was visible something like the tumor presented in the last case. I inserted a trocar into the tumor but found nothing; I incised the tumor about an inch and a half deep and examined it with my index finger, but still got nothing. Her condition was such that I did not care to push the operation further, and sent her home. She had at the time of the operation a pulse of 130 to 140, and went on the table with this. Six months afterward I saw her with pulse of 80, and told her I would like to make another examination, as I could not make myself believe that there was not a cyst. I told her I would like to introduce the aspirator needle. I introduced the needle and drew off three gallons of fluid; returning in about ten days I drew off two gallons minus 1½ pints; making a total of five gallons minus 1½ pints of fluid, which still left her with a tremendously enlarged abdomen. The measurement of this young woman was fifty-two inches around the largest diameter of the abdomen, the tumor reaching to the ensiform cartilage.

I have carefully weighed all of the fluid withdrawn and will be able to determine accurately in the end how much the tumor weighs.

---

CASE OF PRECOCIOUS DEVELOPMENT.

Dr. J. L. Howard: This patient is a little girl eleven years of age who has a good family history; her hygienic surroundings however are not very good. About a year ago she suffered a great deal of pain and tenderness over the mammary region. About the first of June she had distinct hystero-epileptic attacks, very marked, motor convulsions, general opisthotonos, etc. I did not see her until she had had three or four of these attacks. Soon after the first attack she had a hemorrhage from the bowels; without having any fecal evacuation she would have several small stools, probably ½ dram of blood each time, mixed with a good deal of mucous. At first I thought it was a case of membraneous enteritis. Whenever she would have one of these attacks it would be preceded by a hystero epileptic attack, and at the same time she would have this marked tenderness over the mammary region, very painful to the touch. About this time I also noticed a swelling over the mammary region. You will notice she is very poorly developed for her age, and I thought the case would be one of some interest. Dr. Bullock has seen the case with me. It looks like a case of precocious development; she is still having the peculiar attacks; passed some blood to-day. This hemorrhage from the bowels recurs about every two or three weeks without any regularity, lasting probably from twenty-four to thirty-six hours. There is now some swelling of the mammæ, but sometimes it is more marked. She has had scarlet fever, measles, whooping cough and all the diseases peculiar to childhood. I was not able to determine what the attacks were until finally I saw her in one.

The question in my mind has been whether this condition of the mammary glands had anything to do with the hemorrhages from the bowels. They will run their course of twenty-four to thirty-six

hours in spite of anything I have been able to do. No microscopical examination has been made of the stools, but the material has the appearance of stools in membraneous enteritis. The patient is very anaemic as you see.

DISCUSSION.

DR. T. S. BULLOCK: The mammary glands are not nearly so much enlarged or engorged as when I saw the patient about two weeks ago. I have taken considerable interest in the case from the fact of the periodical loss of blood from the bowels, and have been somewhat puzzled to determine the nature of this hemorrhage. The only conclusion that I could arrive at was that it is one of those extremely rare cases of precocious development.

DR. D. T. SMITH: I would like to ask Dr. Howard his reason for pronouncing the convulsions hystero-epileptic. Hystero epilepsy is quite a violent affection, and outside of France is rather rare.

DR. J. L. HOWARD: I simply pronounced them hystero-epileptic for the reason that they were violent, much more so than hysterical attacks. When these attacks come on she will fall down just like we know people do in epilepsy, but she does not froth at the mouth. The attacks simulate epilepsy to such a marked extent that we could not tell the difference until we tried to rouse her. At one time I started to give her chloroform and she immediately came to herself. After that I only had to talk to her of administering chloroform and she would return to her senses.

---

Dr. T. S. Bullock then read a paper on

URETHRAL GROWTHS, WITH A CASE.

The urethra of the female is more prone than that of the male, to be affected with new growths. They are divided according to their structure. The most frequent are what are denominated carunculæ, and polypi. The carunculæ almost without exception grow from the mucous membrane of the urethra, and are invariably excessively sensitive. The patient complains of intense pain on micturition, sexual intercourse, in walking and upon the slightest contact with the clothing. Pain is increased by the warmth of the bed, and the patient becomes extremely nervous and hysterical. Rarely, however, does serious mental trouble ensue, though one or two cases of suicide are recorded. Polypi in this situation vary in size from that of a pea to a hazel nut. They are usually pedunculated and bleed readily, and are very sensitive. Their most frequent seat is the external orifice on the posterior wall a short distance from the entrance.

Carcinomatous neoplasms are extremely rare and are usually the result of extension from the vulva or vagina. Venous angeiomata affect the urethro-vaginal tubercle, or the anterior half of the urethro-vaginal septum. Not infrequently it attains a large size and projects between the labia. It is not at all sensitive.

Sarcoma—only one case reported.

Prolapse of the urethral mucous membrane, or eversio urethræ is not common. In addition to the prolapse of the mucous membrane, there is a proliferation of the connective tissue. It is met with both in the young before the age of puberty, and also in old multiparæ. In the latter it is thought by Dr. Emmet to be due to pressure during labor, by which the tissues are forced into the urethra from behind causing dilatation of the canal, either partial or extending to the outlet. At the same time there is a laceration of the submucous tissues. The tissues at the neck of the bladder are free and by pressure of the child's head are crowded into the urethra in the same manner as the rectal tissues are rolled out of the anus. This condition may exist for a long time without symptoms, but as a rule after a time it develops extreme sensitiveness and soon creates difficult and painful micturition, pruritus vulvæ and leucorrhœa.

Fibromata also occur. They are painless, have a smooth surface and are elastic. A word as to the diagnosis of urethral neoplasms: Carunculæ can only be confounded with two conditions, one is prolapse of the urethra, and the other syphilitic warty growths. From the first it is distinguished by careful examination, which will reveal the fact that it completely encircles the meatus. From the second by the presence of other evidences of syphilis around the vulva and on other portions of the body.

Urethral venous angeioma is recognized by its color and lack of sensitiveness. Fibromata by their smooth surface, elasticity, painlessness and the fact that they do not readily bleed on manipulation.

Many of these growths may exist without causing trouble. This is the case with small condylomata. fibromata and mucoid polypi. If they attain any size the first symptom is a disturbance in the excretion of the urine. Later, pain in micturition, pruritus, frequent desire to void the urine and dysuria. As the growths enlarge the urethra is dilated, the mucous membrane becomes hyperæsthetic and hyperæmic, and a catarrhal inflammation is set up. Following this are erosions and fissures.

*Treatment:* If the growth causes no trouble, non-interference is the rule; but if it causes pain or disturbance of function it should be removed. This is best accomplished by excision followed by thorough cauterization with nitric acid, or better still the actual cautery.

The case which I present, is, I think, an interesting one. It is a fibroma. The following is the history elicited:

A. T., aged thirty-two years; came to the University Clinic complaining of "female trouble;" menstruation regular, slightly painful, three to five days in duration, amount of blood lost normal. Has had four children, the last one fourteen years ago; has had two miscarriages, the last two months ago. All of her labors natural; general health good.

Examination reveals a tumor protruding from vulva; it is two inches in length and is attached to the posterior half of the meatus urinarius. It is lobulated, smooth, dry, elastic and painless. The urethra is very sensitive and an attempt at catheterization occasions great pain. She states that she has no pain on micturition, sexual intercourse, or any other symptom traceable to the growth. She says she first noticed tumor two years ago, at which time it was as large as at present. If the statement is true she certainly gives herself little concern about her genito-urinary organs. Except that it is unsightly and may eventually cause trouble by its increase in size; no interference is necessary.

DISCUSSION.

Dr. J. G. Cecil: This is such a rare growth, so entirely unlike anything I have ever seen, that I really have no opinion about it. I believe, however, that it ought to be removed with the knife, and I think it will require a microscopical examination to determine the exact nature of it. The question has arisen as to whether this is a tumor of the urethra or not. The base of the tumor occupies or about covers the space between the meatus and the anterior vaginal wall, yet it seems to occupy or involve certainly the lower half of the urethral circle. I should judge that its character was certainly very different from that of common growths which we see in this region, and would be disposed to think that it would probably show up under the microscope as a fibrous growth.

Dr. W. L. Rodman: I think that this growth can be called a tumor of the urethra because it is encroaching upon the lower floor of the canal, but I do not think it had its origin in the urethra; I think it began below. I believe it will prove to be a fibrous growth. The growths that are most liable to occur in the female urethra are the ordinary caruncule. The growths that occur most frequently in the male urethra are the ordinary papillomatous growths in the penile portion, and the true fibroid polyp, which occurs almost invariably from the prostatic urethra. This I think is a fibrous growth, but fibromas are very uncommon in the female urethra. They are also uncommon in the penile portion of the male urethra being almost invariably limited to the prostatic portion. For this reason and from the appearance of the growth, I think that it began below the urethra, and has simply encroached upon it secondarily. It is an hypertrophied caruncle.

Of course, the treatment is excision as Dr. Bullock says, and the application of some cautery afterward. The best treatment for the ordinary caruncle I believe to be scraping off with scissors and then the application of chloride of zinc, which I prefer to all other things and believe it is the best application that can be made. It is very fortunate that all tumors of either the male or female urethra are nine times out of ten located in the extreme anterior portion, as otherwise it would be very difficult to treat them surgically. The only exception being the fibroid-polyp which I say is almost always limited to the prostatic portion. Necessarily these tumors usually give rise to a great many distressing symptoms, pain, etc. But it is a fact that you may have tumors even deeper situated in the canal with almost no symptoms at all.

I have seen a number of growths of the female urethra, but few in the male.

Dr. E. R. Palmer: The removal of the growth in the case shown by Dr. Bullock could certainly be very easily accomplished. I would suggest that it be done by cocanizing the parts, cutting it off and the application of electro-cautery. I do not think the growth involves the urethra at all.

I do not agree with Dr. Rodman in regard to growths of the urethra: In the daily use of the urethrascope it is not infrequently that I find tumors of the male urethra situated back of the cut off muscle.

Dr. Turner Anderson: I examined the growth under discussion at Dr. Bullock's office yesterday, and cannot agree with the gentlemen who have spoken that it is not a urethral growth. When we consider that there is no space practically between the meatus urinarius and the anterior margin of the vagina, that the urethra lies in the anterior wall of the vagina, the meatus urinarius is simply surrounded by condensed areola tissue, we must conclude that this is either a growth of the urethra, or a growth of the anterior wall of the vagina. I made a careful examination of it to determine whether it was a growth of the urethra or of the vagina, and so far as I am able to form an opinion it springs from the posterior semi-circumference of the urethra. Dr. Bullock has very accurately described the case, and I am convinced that it is fibrous in character.

As regards removal, there would be no difficulty in doing so, and it is not necessary to discuss that part of the question. There would be very little hemorrhage, as it is wholly disconnected with the vestibule. Operations in this situation are not attended by much hemorrhage unless we open the net work of vessels which are recognized as the bulbs of vestibule. I think if the gentlemen who believe that the growth is not connected with the urethra will make a more careful examination of the case, they would be convinced this growth springs from the posterior portion of the semi-circumference of the urethra, and is fibrous in character.

Dr. W. O. Roberts: I agree with what Dr. Anderson has said in connection with the origin of the growth, and also as to the treatment. It seems to me that removal with the knife would be very much better than with galvano-cautery. I think there would be practically no hemorrhage, and the result would be better with the knife than with cautery. Experience goes to prove in amputation of the penis for instance, where there is liable to be very much more hemorrhage than in the removal of this growth, results are far better when amputation is done with the knife than when done with galvano-cautery and the danger from sepsis seems to be less with the knife.

Dr. T. S. Bullock: As stated in my paper, my reasons for believing this to be fibroma was that most other growths in this situation bleed very readily on handling and are very painful. Fibromata are the only growths occuring in this situation that are absolutely painless, smooth, elastic nonfriable, do not bleed, and occasion absolutely no inconvenience unless they attain a considerable size and drag on the urethra, thus creating trouble by their weight.

In regard to treatment, if I can get the patient to consent, we intend to operate upon her at the University Clinic before the class, but I think we will have some difficulty in getting her to consent to the procedure.

As regards the growth being hypertrophied carunculæ—it seems to me if this had been the case she would have noticed it long prior to two years ago.

---

### SUPRAPUBIC CYSTOTOMY, WITH REMOVAL OF THREE STONES, ONE ENCYSTED, FROM THE BLADDER—RECOVERY.

Dr. W. O. Roberts: The early part of June I was asked to see a case in consultation with Dr. E. R. Palmer for stone in the bladder. The patient was sixty-seven years of age and had been complaining of bladder symptoms for three years. He had been treated by internal medication for one year without any benefit, then he was treated by another physician by washing out the bladder with boric acid solution and using a catheter. He passed water very frequently and soon after he began to use the catheter, he had to use it every few hours. At the time I saw him with Dr. Palmer, he was using the catheter every two hours; he had not suffered any great pain, nor did he have any marked symptoms of

stone. Dr. Palmer had discovered the stone a short time before I saw the case with him. He told me at the time that he was under the impression that the stone was a large one, and most likely encysted. We made a careful examination under cocaine with a sound, and came to the conclusion that there were two calculi. His prostate was examined through the rectum and found to be quite large, but there was no enlargement of the third lobe. Operation was advised, and owing to the large size of the prostate we agreed to do the suprapubic cystotomy. On the 23rd. of June, the operation was performed at the Norton Infirmary, Drs. Palmer, Yandell, Pearce and several others assisting. The bladder was not contracted, we could easily get into it eight or ten ounces of boric acid solution. As soon as the bladder was opened I found two calculi, the smaller of the three here presented, lying loosely in the bladder; after their removal passing my finger high up to the fundus on the left side, I discovered the largest stone presented which you will see is very rough, the rough side of it being adherent to the bladder. After detaching and removing it there was a considerable oozing of blood. The bladder was drained for forty-eight hours by strips of iodoform gauze introduced and left hanging out of the abdominal wound. The patient has gotten along uninterruptedly well, and while he went for two years without passing any water, yesterday he passed naturally a small quantity.

DISCUSSION.

Dr. E. R. Palmer: The case reported is one that has interested me very deeply. I think Dr. Roberts failed to emphasize the fact that the clinical symptoms of stone were entirely absent. The patient is a very charming old gentleman, but like most old men very set in his views and opinions of things; he had been assured that his trouble was cystitis and had been treated by washing and internal medication, and was very much set against instruments. He had never had the sudden cut off in urinating, never had any pain in the glans penis. He had none of the symptoms that would point to cystic calculi. A remarkable feature of the case to me was that for eighteen months he catheterized himself about twelve times per day, about every two hours. He is the father of one of our leading druggists and from whom he had learned the virtue of surgical cleanliness. As he had not passed any water voluntarily for eighteen months, and had been washed without any benefit, I told the druggist that his father must be examined with proper instruments. In passing a steel sound No. 29 French, I was struck with the fact that as soon as I passed it through the cut-off muscle the sound almost dropped into the bladder. The posterior urethra, instead of being constricted by the middle lobe or contracted by general prostatic enlargement, was exceedingly roomy. As the sound dropped into the bladder, it struck a calculus, which delighted me very much because of my belief that we could assure him of decided relief, if not complete cure of his condition. I explained the necessity for operation to both the patient and his son. Dr. Roberts was then in Omaha and I advised waiting until he returned, and then that he be called in consultation. The first stone detected was the large one in the fundus, the second stone I am certain was in the middle zone of the bladder and the third was not found until the operation. The total weight of the calculi removed was about eleven drams, a considerable amount of material being lost with the fragments brought away by washing the bladder after the operation.

In regard to the symptoms, of course one of the best symptoms of stone is *stone*, but this gentleman presented none of the classical symptoms pointing toward stone in the bladder. While they might have been found sooner if his bladder had been examined, yet the doctor who failed to find stone is perhaps excusable for not having done so because of the fact that all the characteristic symptoms of stone were entirely wanting.

Of course the question arises whether there will be complete restoration of the powers of discharging urine. This is dependent upon the recovery of tone on part of the bladder. I believe that his frequent catheterization has preserved his bladder tone although he is nearly seventy years of age. I was more positive and more confident of this than was Dr. Roberts, and I believe he will recover his powers of urination. I was very much delighted last night to hear his son say that his father had passed some water and

that he goes eight hours without emptying his bladder. My instructions were that when he began to feel like emptying his bladder, to place his hand upon the opening not allowing the urine to escape there and attempt if possible to establish a restoration of the normal flow. He, like a great many of our patients, wanted a guarantee of complete restoration, complete cure, etc., but he says to-day that if he does not recover his powers of urination, has to go through the balance of his life with a fistulous opening, he is extremely delighted that the operation has been performed.

Concerning the question of asepsis and antisepsis—if there ever was a case in which the work was done with extreme care, it was the operation in question. No one came in contact with the case except Dr. Roberts and myself, and we both cleansed ourselves most thoroughly and absolutely, instruments freshly sterilized, and every precaution taken, no towel even was allowed to be touched by any assistant, and yet twenty-four hours after the operation the patient had a tympanitic belly, great pain, temperature 90°, and we were naturally very much alarmed. However, it proved to be nothing more than ordinary flatulency of the bowels, which we learned the patient had been subject to before the operation. The man complained of nothing that would suggest the fact that he had had a capital operation performed upon him. The bladder was not seen in the operation, but in attempting removal of the largest stone the incision had to be slightly enlarged. The result in this case I am certain will demonstrate, as has been demonstrated so often, the value of absolute care in work of this kind.

---

CONTINUED REPORT.

I exhibited at the last meeting of this Society, a young man having a serpiginous chancroid on the penis and sore in the right groin. The patient called at my office to-day and the place in his groin was perhaps ⅛ of an inch in height, if anything a little longer than it was when I saw it two weeks ago, and certainly very much less promising in the matter of cure than it was when he was before the Society two weeks ago. He has had this trouble for more than a year, and to-day we seared the whole surface with electro-cautery. We seared the chancroid on the penis about a week ago; it is not much better. To day we treated it as I am treating some tuberculous glands of the face with creosote with the hope that we may get the local and specific action of the creosote on any tubercle bacilli that may be at work and keeping up this trouble. The young man in question is otherwise in good health, and the sore on the penis together with the one in the groin have existed for something over a year. They have resisted every possible mode of procedure in the matter of cure that we have employed, and we have tried almost everything.

DISCUSSION.

Dr. W. O. Roberts: In connection with this case, speaking of the long duration of chancroid: I saw one in a young man that existed for something over a year, and his penis was finally amputated, when complete recovery took place. Amputation was done under the impression that it was an epithelioma. I have another case now that has been in existence for eleven months. A considerable portion of the penis had been destroyed.

---

**Don't.**

Don't try to work on the editor's sympathies. If he is a good editor, he keeps his feelings in the background, and has an eye single to business. His duty is not to relieve distress or gratify individuals aspirations, but to entertain (and, if possible, sometimes instruct) his readers as well as he can. A magazine is not an eleemosynary institution.

Don't ask the editor to tear up or burn your article if he can't use it: decent people dislike to destroy other people's property. Don't fasten all your hopes on a single publication, when their are hundreds of them in the land: what is unavailable to one may suit another. Don't try to hold one person, or set of persons, responsible for the success or failure of your literary career.

Don't complain that the periodicals, while heartlessly rejecting your story, or sketch, or verses, have published hundreds that were worse. Perhaps they have; but when you come to conduct a magazine, you will find that one style of writing or thinking can't be made to cover all the ground, and that your individual taste must defer to that of the public.

# THE MEDICAL AND SURGICAL REPORTER

ISSUED EVERY SATURDAY

ADDRESS
Care P. O. Box 843, Philadelphia.

HAROLD H. KYNETT, A. M., M. D.,
Editor.

RODERIC C. PENFIELD,
Publisher.

316 = 18 = 20 North Broad Street,
PHILADELPHIA.

**TERMS:**—Five Dollars a year, strictly in advance, unless otherwise specifically agreed upon. Sent three months on trial for $1.00.

**REMITTANCES** should be made payable only to the Publisher, and when in sums of Five Dollars or less, should be made by Postal Note, Money Order or Registered Letter.

**NOTICE TO CONTRIBUTORS:**—We are always glad to receive articles of value to the profession, and when used they will be paid for, or reprints supplied, as the author may elect. Where reprints are desired, writers are requested to make a note of that fact on the first page of the MS. It is well for contributors to enclose stamps for postage, that the articles may be returned if not found available.

SATURDAY, SEPTEMBER 9TH, 1893.

## EDITORIAL.

### THE PAN-AMERICAN MEDICAL CONGRESS.

The current week has witnessed a gathering of scientific men which is of more than national interest and which is of first importance to medical science in the western hemisphere. Even the meeting of the International Congress, held in this country some years ago has been of less benefit to America than will be the results of this Pan-American Medical Congress. Without any disparagement of medical science abroad, American physicians have been too prone to overlook the superior merits of American medicine and surgery, and to meekly receive as having authority anything labelled imported and warranted genuine. Of recent years there has been a growing disposition on the part of the American profession to assert itself, and the Pan-American Congress has already served notice on our erstwhile teachers that we are no longer merely pupils but that we have acquired the ability and the resources, and are desirous of working side by side with them for the advancement of the science we are mutually devoted to.

To Dr. Chas. A. L. Reed, of Ohio, the General Secretary of the Congress, more than to any other individual is due the credit for originating and carrying to a successful outcome this meeting of scientists from all countries of the new world. By far the greatest burden of the undertaking has fallen upon his shoulders, and to his persistence, tact and indefatigable energy in overcoming obstacles, and arousing and sustaining interest in the project, the success of the Congress must be accredited.

Aside from the fact that this is the first time that medical men from all American nations have gathered in consultation, this Congress is remarkable for being the first medical convention on this continent which has been recognized and encouraged by financial aid by the national government. Congress appropriated $15,000 for the proper entertainment of foreign delegates. Invitations for foreign governments to send delegates were issued in the name of the President of the United States. Federal medical officers were

detailed to act as delegates. Three hundred delegates were named by the governors of the states of the Union. Delegates were apppointed to represent various medical societies and associations, and finally every physician who could do so was urged to attend and take part in the proceedings of the Congress.

But one general session was held. Thereafter the work was divided between twenty-one distinct sections, each devoted to a specialty. Most valuable discussions occurred in every section but, under existing circumstances, the discussions of the section on marine, hygiene and quarantine will probably prove of the greatest interest to the public. This section, presided over by Surgeon-General Wyman of the Marine Hospital Service, who is also at the head of the National Quarantine Service, considered the question of epidemics, immigration and quarantine, and the relations thereto of governmental control and international regulation. The management and equipment of quarantine stations and methods of disinfection received full and careful attention.

Nearly one thousand papers were listed on the program, but many of these were not presented. The most valuable of these articles and discussions will appear in the REPORTER.

## PRACTICAL QUARANTINE.

A year ago cholera was epidemic in Europe. This year, there is in Europe probably quite as much cholera, and it is spread over a wider area. Last year in the United States, the fear of an invasion of cholera amounted to almost a panic. This year there seems to be little public dread of the disease becoming epidemic. That the country has recovered from its alarm is largely due to the fact that the newspapers have other material with which to fill their columns by stirring up public apprehension over the business outlook.

The popular feeling of security arises from the fact that attention is not constantly and sensationally directed to the danger. But there is a real reduction of the danger of cholera invasion due to the enforcement of the national quarantine laws, enacted by Congress last February. It was fortunate for the country that the initiation of the new laws was intrusted to the Supervising Surgeon-General of the United States Marine Hospital Service, Dr. Wyman, who has so thoroughly and intelligently established the new order of things that if danger has been at all imminent it has been met and overcome without creating any public apprehension.

Briefly stated the law empowers the Supervising Surgeon-General United States Marine Hospital Service, to oversee all local quarantine authorities; to see that these are efficient and careful, and whenever in his discretion he deems it necessary, to supplement the local work or to take entire charge of it. Otherwise he is to merely advise with the local authorities—not to interfere with them.

Perhaps the most valuable provision of the law is that one which empowers this officer to send abroad to infected ports, assistants, who shall inspect all persons about to come to this country, and give to each a bill of health, without which no passenger can pass the quarantine line into this country. The assistants are officers of the Marine Hospital Service, and have been detailed to serve in the consular offices at Hamburg, Bremen, Rotterdam, Amsterdam, Antwerp, Southampton, Liverpool, Havre, Marseilles, Genoa and Naples,—the principal ports of emigration to this country. As Dr. Wyman has said: "This is a new depart-

ure in quarantine—quarantining in foreign lands—and the ultimate result may be looked for with great interest. Whatever the result may be, certain it is that the presence of these officers in European ports has diminished in a great degree the danger of the introduction of cholera and other diseases from those ports. Their relations, in one or two instances, were in danger of being strained, but this danger has been averted both by their tact and good judgment, and because of the all-powerful United States law, which practically says to foreign officials that should they object to the official acts of these officers, the alternate is the refusal of the bill of health and the cutting off of all commerce between their ports and the United States."

United States consuls in the interior are directed to notify consuls at port of the existence of contagious disease in their localities, or when merchandise or passengers are leaving any section within their respective consulates. Cable reports are sent to head-quarters.

At an infected port or coming from an infected locality, steerage passengers must remain under medical observation for at least five days and their personal effects must be disinfected by steam. Cabin passengers at infected ports, must give proof as to abode during the four days immediately preceding embarkation. If necessary they may be detained and their baggage disinfected. Certain articles of bedding, clothing and merchandise cannot be shipped from an infected port during the prevalance of an epidemic, nor for thirty days after it has been officially declared at an end. At all times rags must be disinfected before shipment to the United States.

When one embarks each emigrant is given a card containing certain information regarding himself and bearing a serial number referring to the manifest which is required by the immigration regulations and which contains fuller information regarding the holder. This card must be stamped at the consulate, again at the quarantine at the port of arrival, again at the immigration depot, and must be retained by the immigrant until he reaches his destination. These cards, together with labels upon the baggage, furnish valuable information to the health officers of the interior states.

The president has the right to restrict or prohibit the entrance of individuals or property coming from such places as he may designate, and to maintain the prohibition so long as by reason of the existence of contagious or infectious diseases in that locality he deems it necessary.

At ports of arrival in this country the precautions are as thorough as it has been possible to make them in the time elapsed since the law went into effect.

The great Canadian border which would seem to offer easy entrance for an epidemic is protected by the Canadian quarantine, which along the St. Lawrence River requires all emigrants, whether or not exposed to infection, to undergo examination at one of the quarantine stations, and to have all baggage disinfected. As a matter of courtesy, U. S. M. H. officers are stationed at Quebec for the purpose of inspecting, disinfecting and labelling baggage, and issuing certificates to immigrants to the United States.

This system, inaugurated and enforced with all the prompt, impartial carefulness, and the high degree of skill that characterizes the medical services of the national government, has thus far proved an efficient protection to the United States from the invasion of cholera. It would be wise to see how it would work when applied to yellow fever.

# TRANSLATIONS.

## SYRINGOMYELIA ARTHROPATHIES.†

In *Le Progrés Med.*, April 29, 1893, Charcot reviews the various arthropathies dependent upon syringomyelia, and which are, as a rule difficult of diagnosis. In the evolution of these complications of locomotor ataxia, the tabetic arthropathies develop rapidly, frequently resulting in dislocations of the affected joints, and often preceeding the other symptoms. Charcot presents the history of a young man, 29 years of age, non-syphilitic, but the son of an alcoholic and grandson of an epileptic who was afflicted with destructive arthropathies of rapid development, having caused in a few days the dislocation of two large articulations. The question arises, are these joint troubles early symptoms of tabes, or in other words, are these tabetic arthropathies? It must be remembered that there is at least one condition in which the arthropathy of ataxia may be closely simulated even in its minuter details, and that is syringomyelia. In the course of this spinal affection may occur not only spontaneous fractures such as are seen frequently in tabetic patients, but also destructive arthropathies of rapid development, at times fondroyant and that appear to differ in no essential respect from tabetic arthropathies. A patient 32 years of age, a butcher by trade, when 25 years of age was affected with an extreme hypersensitiveness of the fingers (especially the points) which persisted for some days and then disappeared. The patient then commenced to complain of his limbs, the articulations of the lower limbs first and then of the upper becoming the seat of acute, rapid, lancinating pains causing him to cry out. These pains were entirely spontaneous. They were not produced nor influenced by movements of the joints, and the patient could use his joints without trouble. Sometimes one joint was affected, sometimes another, in the limbs, but never did the pains appear in the body of the limb nor in the trunk nor head. There was no swelling of the joints, no fever, no modification of the general health. This crisis lasted three months.

In May, 1892, seven years after the first attack, the patient suffered from a new onset of acute pains. With this there was discovered a change in the right wrist which became swollen. A month later the right shoulder was found to be swollen, both swellings occurring without any pain. The swelling gradually disappeared, but a deformity occurred in the affected joints gradually becoming more marked. In the wrist there was a subluxation of the carpus towards the anterior face of the bone of the fore-arm. By drawing firmly upon the hand this could be reduced, and this without producing any painful sensation. The bony extremities were increased in volume and there was some crepitus. The soft parts were in a normal condition. The shoulder was equally deformed. There was excessive mobility and the humeral extremity could readily be dislocated under the coracoid apophysis. On palpation in the neighborhood of the elbow, two foreign bodies could be discovered; one appeared to be situated below the beak of the olecranon in the tendon of the triceps, independent of the articular extremities and perfectly mobile; the other, more voluminous, manifestedly seated in the thickness of the triceps muscle, elongated in form. This patient was afflicted not with tabes, but with syringomyelia.

As regards the pathological anatomy of syringomyelia it is characterized essentially by the formation of a cavity with gliomatious walls on the gray substance of the spinal cord. This lesion, which most particularly develops at the level of the cervical enlargement, invades step by step the anterior and posterior forms of the gray substance (polio-myelitic symptoms), finally destroying the white columns, lateral or posterior (leuko-myelitic symptoms). The most common clinical form of the disease is the progressive muscular atrophy, beginning at the thenar and hypothenar eminences with fibrillar tremors, which are the first to attract attention. This atrophy is generally accompanied by sensation troubles consisting mainly in more or less complete loss of sensibility

† Translated for THE MEDICAL AND SURGICAL REPORTER by W. A. N. Dorland, M. D.

to pain, heat and cold, the tactile sense and the muscular sense being preserved. A third group of symptoms corresponds to a series of cutaneous or sub-cutaneous lesions, bony or articular which are designated under the general name of trophic troubles; they include bullous eruptions, edemas, spontaneous fractures, and arthropathies. The latter are vegetating arthropathies, quite comparable to those which are seen in the hypertrophic form of tabetic articular lesions. These generally develop spontaneously, without any traumatic history; the onset is abrupt, at times fondroyant; without pain, without fever, the articulation and peri-articular soft parts rapidly tumify, the ligaments relax, the joint become loose, and dislocation occurs. On moving the joint crepitation may be elicited. The patients do not suffer. The articulations may be moved, palpated, dislocated without producing any discomfort. Contrary to the tabetic arthropathies which most frequently are situated in the lower limbs, (76 per cent. according to Schrotter), the syringomyelic arthropathies affect generally the articulations of the upper limbs (wrist, elbow, shoulder). At times they appear precisely in advance of the disease, but ordinarily, they are preceded or accompanied by other syringomyelic symptoms, trophic cutaneous troubles, thermo-analgesia, amyatrophy, etc.

From an anatomical point of view these may be distinguished as for the tabetic arthropathies, two varieties, the *atrophic* form, which is rare, and the *hyper-trophic* form which is most common. In the latter the ligaments and the capsule are elongated or destroyed and the bony extremities become movable to excess and loose and rattling. The articular surfaces eroded in places, become deformed either because of partial fractures that result, or because of the bony vegetations that surround them.

# ABSTRACTS.

## AMERICAN INEBRIATE ASYLUMS.

Dr. Crothers read an elaborate paper on this subject before the neurological section of the American Medical Association, June, 1893. The following is the closing part of the paper.

The most careful authorities of this country and Europe agree in the statement that fully one-third of all cases who come under treatment for periods of three months or more are permanently restored.

Other institutions, where inebriety is treated as a vice or by empirical methods, claim 80 and 90 per cent. of recoveries.

It is needless to add that all such statements are not supported by published statistics.

In view of the chronic character of these cases, and the imperfect means of treatment, the results so far are encouraging, and indicate great possibilities in the future from a better knowledge and control of these cases.

Such is an outline view of the history and present condition of asylums in this country. The rampant empiricism which is so prominent to-day is indirectly rousing up a new interest in all asylums for inebriates.

The increasing crowds of relapsed cases, whose faith in the gold cure specifics have been misplaced, are rapidly filling up all asylums, and come in a measure prepared to accept physical treatment, and to appreciate the needs of means and remedies. There are ideals of the coming means and appliances essential for the successful treatment of inebriety, towards which a few institutions are struggling. Each year's experience brings larger and clearer conceptions, and each institution is becoming more adapted for scientific work in this field.

An outline of the scientific treatment of inebriety in asylums in America will describe some part of the treatment common to each, but not yet attainable in its entirety, because of the numerous obstacles and want of support from public opinion and other conditions.

The situation of an asylum in the subburbs of a city or in the country near

large centres, with ample grounds for retirement and quiet living, is essential. A proper building, equipped with baths and all the appliances for comfort, with means of amusement, joined with ample legal power to hold the patient a year or more, are equally essential.

They should be called hospitals, not only in full recognition of their physical disabilities, but as places where every condition of life can be regulated and every surrounding can be made to aid recovery and restraint. Literally, a quarantine hospital, where isolation and removal of all the exciting causes, combined with appropriate treatment, to build up and restore the deranged functional activities of the organism, can be obtained.

The time of treatment should be from six months to two years, and be governed by the condition of the patient, and extend to a legal control on parole for a long time after leaving the asylum.

In Connecticut the law gives control over all committed cases for three years, whether on parole or otherwise, in the limits of the State.

The hospital should provide exact military restraint, with duties and responsibilities, rewards and punishments, suited to the condition and capacity of the case; also work, amusement, and occupation, both mental with physical, as medicinal agents. Every condition of life should come under exact military control. Baths, exercise, sleep, food, and medicines, all to be regulated and applied uniformly. Each one should be treated as suffering from profound disease of the brain and nervous system, requiring long rest and building up. The general treatment should begin with an examination and enquiry of the facts concerning his past life and present condition. These conditions should be repeated every few weeks, because of the rapid changes and errors which are impossible to guard against in the first and other examinations. The use of spirits should generally be abandoned very early in the treatment, and the return of the drink paroxysm anticipated by the use of drugs, baths, exercises, and special control.

Many of the paroxysmal drinkers are practically epileptics and require similar treatment. They are suffering from grave disturbances of the physical centres, and physical remedies are required in addition to other means.

Other cases are delusional maniacs and paranoiacs, out of harmony with every condition of natural healthy living, and unable to correct and adjust themselves to such conditions. In others, nerve exhaustion is at the bottom of the drink impulse; inherited tendencies, reflex irritations, and many complex conditions which can only be discovered and treated in hospitals. When these are treated the causes are removed and the alcoholic soil is exhausted and dies away.

States of poisoning from stupor to full delirium are made the subject of special treatment, according to the experience and theories of the physician. These acute symptoms, followed by chronic conditions, require equally special remedies and means.

These are some of the general ideals in treatment to which every scientific asylum is moving. All asylums suffer for want of ample legal authority over their cases for sufficient time to secure permanent results. Public opinion regards asylums as of only temporary, and, in most cases, of doubtful value. But the theories of their work are openly termed "fads," and supposed to be founded on some mercenary or selfish purpose. The pulpit, press, and ultra reformers pass by on the other side, like the Levite. Public patronage is withheld, and most all asylums depend entirely on the income of patients for support. Hence, they are more or less crippled in every way. Many asylums suffer from poor location, bad buildings, and surroundings, inability to classify their inmates, and apply special treatment to each one. In many places baths and systematic exercise cannot be secured. The nutritive, hygienic, and physical treatment cannot be carried out on the ideals of the managers; hence, many asylums are using the means within their power, in anticipation and looking forward for larger and more perfect facilities.

The treatment of inebriety not only includes everything found valuable in hospitals for the insane, in reformatories of the most advanced type, and in the modern sanitarian and homes for neurasthenics. The essentials for treatments in each of these classes are required for the inebriate. The asylum managed on the

scientific plan of providing for the requirements of each case must have the power of control, and special buildings given to the hospitals for the insane; the discipline and management of the modern reformatory and the appliances of the best sanitariums and private homes; then it can approximate to a measure of success in the treatment that at present is only an outline. American asylums are leading the world in these directions of practical work, and while no one has combined only in the crudest way these appliances, many asylums are approaching it yearly. Asylums all over the world are at the beginning and infancy of their existence. A great deal of preparatory work must be done before they can reach the first stage of scientific work. The moral remedies by appeals to the will power and morals of the case must pass away. The delusion and palsy of the higher brain centres must be recognized, and dissolutions beginning in the ethical centres extending down to all the lower faculties must be studied. The great fog banks of metaphysical theories of free will, moral depravity, vice, and wickedness must disappear from all conceptions of inebriety, and its practical management in asylums. Asylums and managers who act on the theory that the inebriate is half-wicked and half-sick are crippled. Asylums and managers who attempt by drugs or moral appeals to restore and cure the victim are still far back in the stage of credulity. The specific vaunter, who professes to break up the the symptom for drink, as if it was the disease itself, is an empiric, either ignorant or by design. Asylums and managers who teach dogmatically the nature of inebriety and its only true remedies are not very far along in their scientific work. Asylums who claim large percentages of cures from certain means and remedies are not worthy or confidence.

Inebriety is found, when carefully studied, to be the most complex neurosis of modern research, dependent on heredity and many physical causes, also physical condition and environment, that are not clear to the most minute study. Asylums for treatment so far, by isolating the patient, places him in the best condition for study of conditions and applying means for relief.

The more thorough this study, the wider the range of causes appear, together with the means and methods of relief. The most advanced asylum of to-day follows a general prospective plan of treatment and has no specifics or no special theories that are not open to change and readjustment, besides a few general facts, which stand out like mountain peaks in a new land, all the intervening space is unexplored. No one can speak dogmatically as to where inebriety begins, and what the exact causes may be. No one can explain the varied phenomena of drink storms, of the action of spirits on the physical brain, of the power of hereditary, of the brain condition which demands relief by the craving for neurotics, of the sudden cessation of this drink impulse, under unusual circumstances, of its equally sudden outburst from causes unknown. Even in asylums the same uncertainty exists. Cases that seem restored, relapse, and others that are considered incurable become restored, showing that our present knowledge is very imperfect, and the known is comparatively nothing in contrast with the unknown.

Running through all this phenomena of inebriety is an outline of a uniform movement of cause and effect; of events following each other according to some law; good examples are the periodicities of the drink impulses, and the outbreak of such impulses from the presence of certain conditions that can be foreseen and studied. Patients under care in asylums present a remarkable uniformity of symptoms and progress that is often startling to the student. Not unfrequently such cases can be anticipated and the results of treatment known far in advance. The drink symptom is dependent on some conditions of brain degenerations and changes. It will suddenly die out and disappear under the most adverse conditions and surroundings. Examples are numerous of persons who become temperate, sign pledges, and stop all use of spirits under the most favorable circumstances. Every temperance and revival meeting furnish illustrations of persons who are restored permanently, although the same means have been used many times before with no result.

Persons are known to stop drinking from the slightest supposed reasons, and

in all these cases the last means used are credited with being the active cause.

The true explanation in all these cases is that some change or evolution of brain function has occurred and the drink system has died out.

It is not the last prayer, pledge, or solicitation of others, or the last drug or remedy of special means used that has caused this change. Other and more obscure causes are at work, and the time comes when their action is apparent in the cessation of the drink impulse. Physicians in charge of asylums recognize this fact, and realize that their best efforts are in building up the brain and nervous system, and placing the organism in the best possible condition for both organic and functional change.

Remedies directed to the drink symptom are never curative; a dose of mercury acting on the liver is a more rational method than bromide to check the drink impulse.

Asylum study of these cases show that inebriety is often a symptom or phase of a neurosis which may break out and change to some other form. General paralysis, melancholy, and many forms of insanity, together with tuberculosis, and various neurotic affections follow frequently on the subsidence of the drink craze.

The statement that the gold cure specifics are followed by an increased number of insane among those who have used the treatment must be a literal fact. The proof of such a statement is found in the experience of every asylum, and the general principles of neurotic diseases. The number of such persons cannot be easily determined, but the more powerful the narcotic used to stop the drink symptoms, the more certain insanity and profound degenerations of the brain centres will follow.

All asylums for inebriates suffer from the large number of incurable inmates, persons who, after an uncertain course of treatment, go away, relapse and condemn the asylum for their failure. Much of the current opinion concerning asylums is formed by the irresponsible statements of incurables. Such persons seem to take pleasure in denouncing asylums in every place, and boasting of the intrigues of its inmates. On the other hand, persons who have received substantial benefit conceal all reference to their treatment and residence in an asylum.

The result is that all institutions are judged by the unthinking public from the statements of those who have failed to receive any benefit from its work.

Unthinking physicians who suppose that the control of the drink craze is the central object of treatment often lend their influence to unfavorable criticism of asylum work. This, joined with bitter condemnations of moralists, complicates and increases the difficulties of every practical asylum trying to understand scientifically this new field of medicine.

American asylums have many advantages over all foreign institutions, in freedom from caste and prestige; also in ability to follow independent lines of work and rise above the prejudices and opposition of those who dread change and advance. Some general conclusions may be stated, as follows:

1. The asylum care and treatment of inebriates began first in this country, and has grown and extended to all civilized nations of the world.

2. American asylums have developed the disease theory and the practical character of physical treatment in institutions beyond that of any others in this field.

3. Asylums in this country represent nearly all stages of development and early growth, from infancy and childhood, with its feeble conceptions and infantile efforts, to the boastful assumption and over confidence of youth, on to the dawning truth of early manhood, when reason and judgment begin to reign.

4. A few of these asylums discern some great outline truths which may be stated with confidence as ideals towards which there is a rapid movement.

5. Inebriate hospitals must take the place of jails and station-houses. Such places are dangerous in their mental and physical surroundings by intensifying the degeneration and removing the patient beyond hope of recovery. They are in many cases literal training stations for mustering armies of chronic maniacs that never desert or leave the ranks until crushed out forever.

6. Inebriate hospitals should receive the incurable inebriates and make them self-supporting, and build them up physically and mentally. They would relieve

the tax-payer and relieve society of untold burdens of sorrow and misery.

7. Inebriate hospitals should receive the recent cases and place them in the highest condition of enforced health and vigor, and thus return a large number to health and sobriety again.

8. Inebriate hospitals can be self-supporting when once established. They should be managed on scientific business principles, like military training schools.

9. Inebriate hospitals should be built from money raised by taxes on the sale of spirits, on the principle that every business should be obliged to provide for the accidents which grow out of it.

10. These are the realities which every inebriate hospital is approaching and which all experience points out as practical and literal in the near future.

11. The enebriate hospitals of to-day are only in the infancy of their work, contending with great opposition and prejudice, misunderstood, condemned, and working against innumerable obstacles.

12. Lastly, there is an intense personality in inebriate hospitals to each one of us. They may bring salvation and restoration to some one near and dear. They may be fountains of healing whose influence shall cross and influence our pathway in many ways.

13. Inebriate hospitals and their work are the great new lands which only a few settlers have reached. They are calling to us to come up and occupy, and thus help the race on in the great march from the lower to the higher.—*Quarterly Journal of Inebriety.*

---

### Ectopic Gestation in Both Tubes.

Walter reports a case of tubal gestation in which both tubes were gravid. On opening the peritoneum there was a discharge of fatty blood with clots. The uterus was enlarged; there was a tense cystic swelling, a little larger than a Tangerine orange, felt in the ligament, and a similar one to the right side and behind the uterus. The tumor on the right side proved to be the right Fallopian tube distended with blood. The left mass was found to present in its outer extremity a tear, exposing a firm blood-clot; this was occupied by an apoplectic ovum and tubal mole. The amniotic cavity presented an embryo six centimetres ($2\frac{1}{3}$ inches) in length; this was so thoroughly saturated with blood that it resembled in color the clot by which it was surrounded. In the right tube the ostium was found completely occluded, its walls intact. In cutting into the mass, it was found occupied by a tubal mole. The amniotic cavity persisted, but no embryo was detected. The wall of the tube and the mole were hardened, and in due course embedded and sectioned for the microscope. Chorionic villi were found in clusters, which demonstrated beyond any doubt that the organized clot in the right tube was a tubal mole. The pregnancy in the left tube was more advanced than in the right. It is impossible to determine whether the pregnancies occurred at the same time,—the one becoming apoplectic and ceasing to grow, or whether it occurred at a latter period.—*British Medical Journal.*

---

### Double Pyosalpinx.

Butler Smyth reports double pyosalpinx, in a woman 26 years of age, in which there was a large, elongated swelling centrally situated, which reached to the umbilicus. This was movable from side to side, but not tender to the touch. The uterus was pushed in front of the tumor, and was distinctly recognized through the abdominal walls. The lower part of the tumor was found in Douglas's pouch. On the left side of the uterus was another fixed swelling, filling the pelvis on that side. The tumors were closely adherent to intestines and omentum, rendering the separation difficult and tedious. They were removed without rupture; which seems to be the preferable plan, rather than to remove the contents by aspiration, as, when the tumor is once emptied, its landmarks are destroyed and the difficulty of the operation increased. In separating a tumor, use the pulp of the finger as much as possible, and thus endeavor to prevent its laceration and rupture. The patient recovered.—*The Lancet*

---

Don't "give it up" because a particular contribution is declined. As you may learn from the circular which all well-conducted magazines send out in such cases, its non-acceptance may be dictated by considerations irrespective of its intrinsic merit or your ability. A second, or a twentieth, shot may hit the mark which others have missed.

# CURRENT LITERATURE REVIEWED.

THE AMERICAN JOURNAL OF OBSTETRICS.

for August.

Dr. Christian Fenger contributes a paper on

**Appendicitis,**

In which the whole question is thoroughly considered and the recent literature on the subject carefully reviewed. The author reports several cases and the paper which was read before the Gynecological Society of Chicago, is illustrated with several wood-cuts of specimens removed. The advice is given to operate, first, on all cases accompanied by general or diffuse peritonitis; secondly, to operate upon the cases wherever a tumor exists in the region of the appendix, which steadily though slowly increases after the first four or five days of its discovery; lastly, to operate upon the cases that are known as cases of recurrent appendicitis, providing such attacks give signs of gravity.

Dr. Fernand Henrotin discusses

**Enterostomy and Drainage in the Treatment of Diffuse Septic Peritonitis.**

In a short article read as part of the discussion of Dr. Fenger's paper, he emphasizes the point that in severe general diffuse septic peritonitis with tympanites, from whatever cause, the chances of recovery will be enhanced if two openings are made, one to drain the peritoneal cavity, and the other, an artificial anus, to relieve the distention.

Dr. Edward Sanders presents a paper on "Chronic Oophoritis and its Treatment by Electricity." The paper presents the conditions of life and other causes of the disease and will be continued in the next issue of the journal.

Dr. Robert A. Murray furnishes a

**Clinical Report of Cases of Pyosalpinx, treated by Uterine Drainage, with Subsequent Conception.**

As a result of the cases observed, he presents the following conclusions:

1. That many cases of pyosalpinx are curable without mutilating operations, if the endometritis be treated by curettage and drainage with strict antiseptic precautions.

2. That true drainage of a pyosalpinx into the uterus is possible and does occur when the tubes and ovaries are on a level with the uterus, and the uterine end of the Fallopian tube is patulous, or can be made so by treating the uterus.

3. That uterine curettage and drainage should be practiced in every case before operation, unless the tubes are very distended and thin, to cure the endometritis, which may and often is a cause of trouble and lack of relief after celiotomy and removal of the organs is performed.

4. That, even after pyosalpinx, frequently the tubes and ovaries are not useless organs, the proof being that pregnancy occurs and the puerperium is normal.

5. That only after proper treatment, the tubes, ovaries, and uterus remaining bound down by adhesions and a menace to life and health, should the radical operation be done.

6. As a matter of observation in large maternities, there are very few cases of puerperal complication due to the presence or results of a former pyosalpinx.

Dr. H. W. Foster reports a "Successful Case of Cæsarean Section."

Dr. Grace Peckham Murray contributes a paper on "Hematoma of the Vulva, with report of a case." The paper is illustrated with an excellent colored lithograph of the existing conditions.

Other papers in this issue are "The Value of Treatment in Pelvic Disease," by Dr. Frieda E. Lippert; "By what Authority are Resections of the Fallopian tubes and Ovaries and the Enucleation of Myomata characterized as 'Surgical Amusement?'" by Dr. A. Martin, of Berlin.

---

THE CHICAGO MEDICAL RECORDER

for August.

Dr. Edward Wyllys Andrews contributes a paper entitled

**Further Experience with a New Treatment of Hemorrhoids**

in which he advocates electro-puncture of the pile. In his first experiments he used a hypodermic needle for the double purpose of injecting cocaine and applying electricity to the tumor.

The present form of instrument contains no provision for injecting cocaine, but could be so arranged by making one of the needles hollow. The destructive action of the current very rapidly corrodes any but a platinum needle, and by using fine dental broaches he obtained almost entirely painless puncture. The hollow needle is so much larger as itself to be a little more likely to cause pain. My experience is yet too limited to determine whether it will be better to rely only on external applications of cocaine. So far I have had little or no pain with the broaches. They corrode very fast, and must be renewed. Theoretically a fine copper electrode would be desirable, as shown by the hardening and penetrating action of the copper salts with the uterine electrode.

He has found this method a pleasant and efficient substitute for the hppodermic treatment. On theoretical grounds, he feels warranted in claiming that it will prove safe, and that the cures will be permanent. Should clinical experience develop no cases of embolism, or other dangerous complications, he believes the method can do what the hypodermic method has failed to accomplish in superseding all operative measures requiring anæsthetics and confinement to bed.

The author includes in his paper the report of a number of cases in which he used the method. He stated that it is not adapted to those cases in which there has been long

continued irritation and much resulting hyperplasia. One feature of the electrolysis is the abatement of pain which the author states has followed the electrolytic treatment.

Other articles in this month's issue are an illustrated paper on "Tait's Perineal Flap Operation," by Dr. F. Byron Robinson; "A Consideration of the Traumatic Neuroses," so-called by Dr. Harold N. Moyer; an interesting account of the "Condition of Siberian Lepers and the Means for their Relief," by Kate Marsden; and "The Leprosy Problem," by Dr. William Allen Pusey.

# PERISCOPE.

## SURGERY.

### Treatment of Pulsating Pleurisy and Pneumorthorax.

Ernest Rowell Watkins, of Notingham, has practiced paracentesis of the chest in cases of pulsating pleurisy and pneumothorax with good effect. In the case of a girl 18 years old, who had strained herself by lifting a box, there was a sensation of something having given way and pain in the side and back. After various measures of treatment a distinct pulsation or heaving was noticed in the thoracic parietes, and the hand, when placed on the left side, was forcibly lifted at each pulsation. Ten ounces of pus were removed from below the inferior angle of the left scapula, and a drainage-tube inserted with ultimate complete relief.

Another case, a clerk aged 26, had "wrenched his insidies" and the pains were referred to the left side. Signs of great intra-thoracic pressure followed, and the left side was distended, with the heart pressed over to the right. The chest was punctured and a quantity of air came away with twelve ounces of fluid. From this time the patient improved, and the breath-sounds could be distinctly heard back and front.—*Lancet.*

### Estlander's Operation in Empyema.

Sir William Stokes, in treating of the conditions under which empyema is developed, states that the results of the experience derived from the cases operated on in Dublin would tend to show that ultimately Estlander's operation will be deemed applicable to a much larger range of cases than at present. He considered it an important matter to determine the point where the opening into the cavity of the pleura should be. He thinks that situated over the ninth rib, recommended by Godlee, is perilously near the diaphragm. He approved of flushing the pleura both during and subsequent to the operation.

In discussing the views of Stokes, it was stated by Heuston that Estlander's operation was required only in cases of very long standing, where there was a space which could not be occluded unless the chest-wall were allowed to adapt itself to the collapsed lung. He turned the flap of periosteum over the end of the rib, where it had been cut across, and this hindered the absorption of the discharge by the cancellated bony tissue, and thus avoided pyæmia.—*Dublin Journal of Medical Science.*

### An Interesting Case of Empyema.

Barlow reports an interesting case of empyema in his service in the children's ward of the University College Hospital. A boy, aged 11 months, had suffered with a bad throat, with swelling of the neck, discharge from the nose, and trouble of his ears. He was admitted into the hospital with a temperature of 104° F., uttering short cries, breathing quickly, and catching his breath, —indications of pneumonia. The upper two-thirds of the right lung were dull, with bronchial breathing and bronchophonic resonance, and the rest of the side gave defective resonance, with weak breath-sound.

A large hypodermatic needle was inserted near the angle of the right scapula, and soon this fluid withdrawn. Under the microscope many pus-cells were seen, and afterwards the presence of micrococci, diplococci, and a few small chains were found. Two days subsequently a free opening was made into the chest, with the removal of a small piece of the ninth rib, and then seven ounces of fluid escaped, and five days latter shaggy lymph came out.—*The Clinical Journal.*

### Surgery of the Thorax.

Rickman J. Godlee, of Bromptom, England, in an address before the British Medical Association, presents points of interest on the surgery of the thorax. As to the site of election for incision in empyema, no position is so good, in his opinion, as that opposite the ninth rib, just outside the angle of the scapula. If the chest be very full, a good plan is to place the patient well over on the diseased side, semi-prone, in fact. It will then be found quite easy to reach the ninth rib outside the scapular line by standing behind. The time of removing the tube depends upon the amount and character of the discharge. If the tube should have slipped in through an anterior opening, the original opening should first be enlarged; and, if not found, it may be necessary to make a posterior incision for its removal.

Double empyema is not so rare as might be supposed. The greater number of pulmonary abscesses encountered by him are bronchiectases, and the treatment has not been very successful.—*The British Medical Journal.*

### A Case of Traumatic Hernia of the Lung.

E. Massart, of Honfleur, records a case of traumatic hernia of the lung. It occurred in a robust, healthy man, 38 years of age, as the result of a stab wound in the seventh left intercostal space, a little behind the anterior axillary line. The protruding lung former, a swelling in the wound of the size of half a hen's egg; it was smooth, of a rosy color irreducible, crepitating under the finger, and not altered in size by the movements of respiration. The wound had occurred fourteen hours before seen, and the patient complained of severe pain in the part, and his respiration was short, rapid, and embarrased. The base of the tumor was transfixed with a needle carrying a double strand of catgut, with which it was tied in two pieces. The projecting mass was then cut away and the stump was reduced into the pleural cavity. The external wound was closed and rigid antiseptic treatment carried out. The man made an excellent recovery, without either pleurisy or pneumonia.—*The Lancet.*

### Antiseptic Intro-pleural Injection.

Sarbony has employed antiseptic intrapleural injection for the treatment of thickening of the pleura with marked benefit. He uses an injection of 20 grammes (5 drachms) of liquor of Van Swieten in acute pleurisy after performing thoracentesis. In sero-fibrinous pleurisies the same method has been attended with remarkably good results. In purulent and encysted pleurisies, and in cases where resolution or absorption cannot be expected, this form of injection is advised.

Another injection has been employed, consisting of iodine 1 gramme (15 grains), iodide of potash 4 grammes (1 drachm), distilled water 35 grammes (9 drachms), which is used daily and continued for eight or ten days. But this is not attended with such satisfactory effects, in the arrest of the pleural trouble, as the injection of Van Swieten's liquor in quantities ranging from 5 to 35 grammes (1½ to 9 drachms).—*Journal de medecine et de chirurgie pratiques.*

### Intra-pulmonary Injections in Pulmonary Tuberculosis.

Gallet condemns the surgical treatment of pulmonary tuberculosis, and objects to antiseptic washes or injection into the parenchyma of the lung, considering them not only useless but dangerous measures.—*La Partique medicale.*

### Purulent Pleurisy Opening in the Lumbar Region.

Dubreuilh, of Montpellier Hospital, r a case of purulent pleurisy opening in the lumbar region. A young man presented an emypema, which migrated to the ileocostal space on the left side, and the lumbar abscess was opened by an incision one and one-half centimetres (⅝ inch) in length, discharging a litre (quart) of sero-sanguinolent fluid. It was washed out with boric-acid solution and packed with gauze.—*Gazette medicale de Paris.*

### Excision of an Hydatid Cyst of the Lung

Delageniere reports a successful case of this character. A large opening in the chest-wall was made, and a portion of the sixth, seventh, and eight ribs was resected; the cyst was then stripped away.—*La Semaine Medicale.*

## GYNECOLOGY.

### Premature Sexual Development.

J. Halliday Croom classifies premature sexual development in relation to ovarian tumors, under the following heads: I. Precocious menstruation with early appearance of the external manifestations of puberty. 2. Sexual development without menstruation. 3. Menstruation previous to the development of the sexual organs. 4. Early conception and pregnancy. 5. Premature sexual development associated with tumors of the generative organs.

Of the first class the most striking illustration is the frequently quoted one of de Beau (*American Medical Journal*, vol xi). The individual was born December 31, 1829, with mammæ perfectly formed and mons veneris covered with hair similar to a girl 12 or 14 years old. The catamenia appeared when she was three years old, and continued regularly every month as copious as in a woman. Each period lasted four days. The dimensions of her pelvis were such as would have permitted her to bear children at three years of age. The second class of cases are infrequent. Among the instances that have been mentioned is one by Cook, in "Medico-Chirurgical Transactions" for 1813. The patient was born in 1802; the external pudenda became prominent and covered with a quantity of dark hair when she was 4 years of age. Within four months of her death, in 1809, she began to suffer from convulsions, after which she increased enormously in weight; complexion became florid, cheeks downy, and lips covered with so much hair that she might be said to have a beard. Her voice, formerly shrill, became strong, and the whole contour was that of puberty, except the breasts and general stature; the mons veneris and labia pudenda were as at perfect puberty, covered with long black hair. Menstruation did not occur, and post-mortem examination showed no change in the external organs of generation. Neither ovaries nor uterus were increased in size. Third: menstruation without development of the sexual organs is less unusual than the preceding, but is also rare. Pozzi alludes to

the case of Bernard in the *Lyon medical*, 1887, of a girl who had menstruated regularly from birth up to 12 years of age without any development of the external organs. Fourth: numbers of cases of early pregnancy have been reported by trustworthy authorities. Muller, in the "Cyclopædia of Obstetrics and Gynecology," reported a case of a girl who menstruated at the second year and was pregnant in her eighth. Fifth, in tumors previous to sexual development, upon which this paper is founded, is the case of Forsythe: a child 7 years of age suffered from a large abdominal tumor. Previous to March, the present year, she had been perfectly well, without abnormal symptoms. In this month she was raped by a boy on several occasions, immediately after which she had a profuse discharge from the vagina, which continued almost uninterrupted until admission to the hospital, several months later; shortly after the rape the abdomen began to swell and gradually enlarged, until, on admission to the ward, she had a tumor about the size of a seven months' pregnancy. It was supposed that this was pregnancy, notwithstanding her extreme youth. This was apparently confirmed by the development of the mammæ well-marked linea nigra, copious development of hair over the mons veneris, and a well-marked bruit was heard. The tumor was freely movable, tense, firm, and had apparently no intimate connection with the pelvis. The mobility and absolute solidity decided against the possibility of pregnancy. The patient was carefully examined under an anæsthetic; the remains of the hymen found thick, completely penetrated; vaginal walls smooth; cervix enlarged, soft, and patulous. The uterus was found to be slightly enlarged, over three inches in length. Manipulation caused free hemorrhage. It was supposed to be a sacculated ovarian tumor. An operation was performed on November 25th. The tumor was aspirated, but only a small quantity of sero-sanguineous fluid withdrawn; had no adhesions; was perfectly free in every direction. Abdominal incision had to be enlarged within an inch and a half of the ensiform cartilage, owing to the fact that the tumor was incompressible. It was removed, and found attached to the left side of the pelvis by a long pedicle. The Fallopian tube was greatly distended and tortuous, the opposite ovary small and undeveloped; the uterus was enlarged, corresponding with the dimensions indicated by the sound previous to the operation. The tumor weighed over six pounds.—*Edinburgh Medical Jnurnal*, February, 1893.

---

### Ovariotomy with Pregancy.

Fancourt Barnes, of London, reports the removal of a multilocular ovarian cyst in which there were adhesions of intestine to almost the whole surface of the cyst and the intestines in a state of acute congestion. The tumor was found to spring from the left side of the uterus. which was enlarged about the size of a four months' pregnancy. The abdomen was washed out with clean, warm water and the wound closed with silver sutures. The patient recovered without interruption of the pregnancy.—*British Gynecological Journal.*

---

### Pyosalpinx Opening into the Rectum.

Veit reports two cases of pyosalpinx communicating with the rectum. The first patient had stricture of the rectum close to the site of the perforation. The suppurating tube was removed and the opening in the rectum sutured. Sterilized gauze was introduced into the abdominial wound for drainage. The patient died, seven months later, of phthisis. The second patient had repeated attacks of pelvic peritonitis. Operation was repeatedly deferred; the tubes were distended, and were removed, and the perforation of the bowel found after careful search. The patient died from obscure symptoms, when a circumscribed peritonitis was found in the pelvis,—an encapsulated cavity, which formed a communication with the rectum by a narrow, tortuous, fistulous tract. Veit thinks that this case would have been saved by drainage.—*British Medical Journal*

## ORIGINAL ARTICLES.

### SOME CONSIDERATIONS ON THE THERAPEUTICS OF DIABETES MELLITUS.

ALFRED EICHLER M. D.,* San Francisco, Cal.

A great many observations on the nature and therapeutics of diabetes mellitus have been collected during the last few years. While in former times it has been thought that those suffering from this disease where of necessity incurable, or in other words, almost candidates for death, a belief has gained ground recently that even this illness can be treated successfully, or with such results that the prognosis need not be necessarily a grave one. Cases of diabetes mellitus may be cured under attentive treatment provided that both physician and patient co-operate, and in no disease is the co-operation of the patient of such importance. From the very nature of the disease it is readily understood that dietetic measures are absolutely necessary to successful treatment; and as the physician can only give indications as to the food to be partaken of, much will depend on how the patient carries out his medical advisers orders and how he obeys the rules laid down for his observance. Of course, the physician also will have to pay close attention to such cases; a slip in the management of a case will often do sufficient harm to cause endless trouble. So long as patients desire to live according to their own ideas and so long as they intend to enjoy such things as they may like, just that long no success is to be hoped for in the treatment of diabetes, and the physician will do much better to leave such cases alone, especially after the gravity of the disease has been duly explained to the patient and after he has been informed that a disease so severe in character as diabetes mellitus cannot be cured by the convenient exhibition of a few pills or a pleasant draught.

Regarding the practical therapeutics of this disease, it should be first considered what object such a treatment should have in view, and what means are at our command to relieve the symptoms and finally, if possible, bring about a cure. The ultimate results to be avoided, or in other words, the direct cause of the lethal end of diabetes may be classed within four divisions:

1. General marasmus, on which some acute disease supervenes and which causes death within a short time—a weakening of the constitution which does not permit the supervening disease to take its way towards recovery. The acute supervening disease may be of the most common nature, as pneumonia or typhoid fever, and does not have its origin at all in the diabetic state; it is to be regarded in the light of an acute complication.

* Physician to St. Josephs Hospital, San Francisco, California.

2. Diabetic coma, caused by the diabetic state, or coma caused by some supervening disease.

3. Changes within the vessels and large organs, caused or favored by the diabetic state, such as nephritis, fatty degeneration of the heart, or changes within the arterial walls leading to apoplexy.

4. Gangrene, either in consequence of wounds or injuries, or within the lungs, caused and favored by the diabetic state.

The object of treatment would be, according to this;

1. To relieve the diabetic state as much as possible, the only means to attain this being the use of a proper diet.

2. To use such therapeutic and hygienic measures as will prevent the occurence of intervening disease and relieve it when already existing.

It is hardly necessary to state that as not all diabetics will fail from the causes above mentioned, it requires somewhat of a diagnostic experience as to the measures to be taken in individual cases. Of course, an anti-diabetic diet should be used in all cases, however light or severe; but as to the proper hygienic methods or drugs to be employed, much latitude can be allowed and much will depend on the individual abilities of the physician. Many will get along without drugs, others must have such functions as are lagging or disturbed restored to proper activity, while in still others the most importance must be given to hygiene.

Generally speaking, diabetics may be arranged under two classes: 1. Those in whom by the observance of a proper diet the sugar in the urine will disappear entirely while such a diet is strictly observed, and in whom after the disappearance it will not return quickly or in very large proportion; 2. Those in whom the sugar in the urine does not disappear even if the strictest diet is observed and most stringent therapeutic measures taken. The former can be called the mild form, the latter the severe form. We assume that in the milder form the sugar is formed in the blood (resp-urine) only after the ingestion of carbo-hydrates, while in the severer form the sugar is also derived from the albuminates. Cases of the latter kind have been observed when the too liberal ingestion of albumen in any form increased the percentage of sugar contained in the urine. It can readily be seen, by the very classification, that there must be a difference in the treatment of the two classes. While a large number of mixed forms also exist, which cannot be classified under either heading, it can be ascertained by repeated examination of the urine, by the observance of a special strict diet, by the general character of the disease presenting itself in the patient, whether the relatively favorable prognosis of the milder form of the disease can be given.

Regarding anti-diabetic diet in general it is noticeable that almost every close observer has his own preferences and of course much difference exists according to the class of cases observed. The strictest diet is perhaps prescribed by Cautain. He permits only meat and fish, no food with even a suspicion of starchy matter, no butter or other fats, no wines; none of those little additions which act as a sort of make believes to the always objecting patient; others are milder in their orders. Naunyn, Ebstein, Pavy, Harley, and many others furnish special tables for the diet to be given in these cases. The main point of all diets, however, no matter how strict or how lax, is this: Daily examination of the urine, with quantitative estimation of sugar, and as soon as an increase or no decrease is noted, back to as strict a diet as the patient will bear. Weekly or bi-weekly weighing should not be forgotten. In all cases it should also be remembered that the quantity of food, even if only animal nourishment or albuminoids are taken, must not be lost sight of. Cases have been noticed, where the urine was free from sugar on the ingestion of a moderate amount of meat, while when an excessive amount was taken, the urine contained sugar. This is also a further proof of the statement that sugar may be generated in a purely albuminoid diet.

Now to get to the practical side of the diet. It is very easy to prescribe for a patient a restricted diet, furnishing him at the same time a statement of what he may eat and what not. I have found a better plan to map out a diet table extending over a whole week, including every day in the week and prescribing the exact kind of food which should be consumed at a meal, and incidentally I

have found that under those circumstances a patient will be much more apt to carry out instructions than when the whole arrangement is left to himself. Of course, he should be furnished with an outline of the treatment, so that he himself may intelligently understand the why and wherefore of the different measures, and thus will the importance of his carrying out his instructions be impressed upon his mind. It is also much easier to revise a diet table occasionally and the patient himself can be furnished with a substitute list, which will answer in case the articles originally ordered may through uncontrollable circumstances not be obtained or pall on his stomach. Additions to the table are easily made and the effect on the system can be ascertained without difficulty. Another point in favor of this procedure. It is a self-acting check on the patient, as the daily examination of the urine will always show any transgression from the permitted diet and the excuse of similarity between different articles of diet so often offered will not hold good.

In the preparation of this kind of a diet table the ability of the physician as a gourmand will often be taxed to the utmost. I maintain that it is possible to please almost every one in the subject of a restricted diet, provided one has the proper culinary resources as well as proper assistance, and further, the goodwill of the patient. No less an authority than Billroth has remarked that a physician should be as well versed in the kitchen—or in other words, in dietary affairs, as he should be in general practice.

I offer for consideration the following two diet tables: The first one a restricted dietary for the milder cases of diabetes, in which there is a prospect of subduing the disease by adherence to the orthodox strict diet, even if it has to be persisted in for a long time. The second is for cases in which the diet prescribed in the first table has failed and which may therefore be put down as belonging to the aggravated form, in which the main point must be put on the maintenance of vitality and strength and not on the diminution of the sugar. At the same time it has been made an object not to offer any more nourishment containing sugar or its controvertibles than is necessary for the purpose, and much weight has been put upon the fact that food somewhat filling in nature avoids frequency in full meals. See tables p. 432-33.

The tables are intended for patients of ordinary means; of course, they could be largely improved for wealthy patients; for instance, poultry and game of various kinds can be added just according to the means of the patient, likewise vegetables not ordinarily obtainable. Here, in our part of the country, we can obtain the vegetables marked down in the above dietary for at least nine months in the year at a very moderate price and the balance of the time at a not extravagant one. The individuality of the patient is also to be considered and much diversion may or may not be obtained according to his individual tastes. Regarding vegetables, a difference of opinion exists among authors. While many will not assist in diminishing the sugar, still they contribute to diversify the diet and make it more bearable, and not do positive harm. There is no necessity for such strictness when equal results can be attained with less severe measures. The alkaline waters may also be used as table waters and will assist in bringing about a better condition. Koumyss, wherever obtainable, can be substituted for the second breakfast and afternoon lunch with advantage. In this connection it should be mentioned that the Koumyss tablets, now to be had everywhere, will facilitate largely the home manufacture of Koumyss and render its employment cheaper for people with rather limited means.

In the tables above given chocolate and cocoa are also ordered; they should be perfectly free from starch and sugar; such preparations can be had in the ordinary channels of trade. Saccharine can be used to sweeten as a substitute for sugar. It is best for this purpose to order a solution of saccharine in alcohol, say about one grain to one drachm, or to use tablets of saccharine one-fourth grain and mounite q. s. The former can be used in half or whole teaspoonful doses, equal to one-half or one ounce of ordinary cane sugar. The latter from one to four tablets at a time. This will cause almost excessive sweetness already, but if more should be desired, further addition would still be harmless.

# FIRST TABLE.

If after one or two weeks' trial the Urine contains only a small amount of sugar, say ½ per cent., strike out all vegetables and insist upon the reduced diet for two more weeks.

Plain or Spanish.<br>Claret, Burgundy.<br>Tea, Coffee (4). |

### FOOT NOTES TO TABLE II.

1. POTATO PANCAKES. To make this culinary preparation, take about one pound of potatoes, grate the same and press through cheese-cloth; this will partly remove the starchy matter. Mix this paste with one beaten egg, two tablespoonfuls of milk, and about six tablespoonfuls of sour cream; add salt and pepper, divide into flat round cakes and bake in plenty of fat.

2. POTATO DUMPLINGS. Press a pound of potatoes as above, beat up with egg, milk and sour cream, as above. Mix well and add to the mass a trifle of yeast, about the size of a bean. Let stand for an hour, form into balls and boil in bouillon, until done, *i. e.*, until they float on top.

3. TOAST. When referred to above, it always intended to give about 2 ozs. at a time.

4. RECIPES for the preparation of all dishes mentioned in both tables can be found in any cook-book with the exception of the above specified ones. For sweetening nothing but saccharine is to be used.

As far as the wines ordered are concerned, it is absolutely necessary that they should not be sweet wines, that is, contain sugar in a free form. Clarets, Burgundys, Bordeaux of the red wines, light Rhine wines, Morelle wine, California, Reisling and very light and mild Sauterne (heavy Sauternes contain much sugar) as white wines are about the only varieties permissible. Beer, ale and porter must be strictly prohibited, only bitter ale as containing a mere trifle of malt being allowed at times. It is best to have all wines and other liquors examined regarding the sugar contained therein before advising a patient to drink the same. Gravies and sauces for the first table must be simply prepared from the meat juices; in the second class, where a strict albuminoid diet is not carried out, a little flour may be added for the purpose of thickening and flavoring.

Regarding bread, it should be remarked that during recent years Ebstein, of Gottingen, has obtained excellent results with a special form of flour called aleuronot which he has baked into aleuronot bread in various proportions with ordinary flour. Its advantage lies chiefly in the better taste, and is reported to be the best substitute for ordinary bread. Any one who has treated a diabetic knows what this means. As yet it is not obtainable in this country, but no doubt soon will be. Such a preparation will enrich the dietary of the diabetic to a great extent and in fact will aid to bridge over the main difficulty. Toasted bread or the crust of fresh roll in limited quantity have often been allowed as possessing less controvertibility than ordinary bread and certainly being of more advantage than the various forms of gluten bread and anti-diabetic biscuits, only too often carelessly prepared and actually useless. Many patients would just as leave chew saw-dust as such biscuits.

Milk or cream may ordinarily be allowed to diabetics; caution should, however, be observed, as it has been demonstrated that an increase in sugar will follow the plentiful ingestion of milk in some cases. As far as the skimmed milk is concerned, it is well known that Doukin maintained to cure diabetes by a strict skimmed milk diet. It may be of advantage in some cases and should be tried when the disease is obstinate. One rule must always be observed in attending to the diet of a diabetic patient. If the patient wastes away on any diet, no matter what, his dietary must be looked after at once; the wasting of his body in flesh and power is as much, if not more, an index for treatment as the quantity of sugar in the urine.

The hygienic part of the treatment should also be given especial attention. Of course, the entire mode of life cannot be changed with all patients. It is well enough to order the patient to lead a quiet life, free from worry, etc., but it is not always feasible to carry out such injunctions. Patients must be instructed to avoid all excess and dissipations, late hours, entertainments which may cause much nervous excitement and such other so-called pleasures of civilization which may not harmonize with the plan of treatment. In regard to clothing, flannels should be worn next to the body, and the patient warmly but comfortably dressed, so as to avoid all unnecessary exposure to colds, which may become quite dangerous in his condition. The skin should be kept clean by frequent baths and douches. Teeth and mouth should be cleansed by the frequent application of tooth brush and water and much care should be given to the general condition of the mouth.

Exercise in the open air must be prescribed for all patients able to be about. It should be used in proper moderation and in the different forms suitable—walking, riding, gymnastics. If the patient is too weak for active exercise, massage may be substituted for it. In patients yet possessing sufficient strength active personal movements will be of more advantage than massage possibly could be. Turkish baths are also useful in the milder cases as they excite the skin and relieve the kidneys somewhat of their work and conduce to the well-feeling of the patient.

Not much can be said as to the efficiency of drugs in the treatment of diabetes mellitus. Many have been tried and equally many have been found wanting. Antipyrine, jambul, opium and its alkaloids, especially iodine, iodoform, salicylic acid and the salicylates, quinine, saccharine, peroxide of hydrogen, arsenic, carbolic acid, the various salts of zinc and the valerianates, all have had

their day and none have been of more than symptomatic value. In fact, medication in this disease is altogether symptomatic.

Cod liver oil deserves in this respect perhaps the front rank, its purpose being to aid in keeping up the vitality of the patient and thus it will always be of value in this disease.

To classify the value of drugs in this disease would be a difficult undertaking; whatever symptom may be the most prominent should receive the most attention. The excessive thirst so often complained of is often quenched by the administration of alkaline mineral waters or by copious cold water enemas; the latter often are very efficacious when other means have failed. The craving after certain foods can be alleviated by occasional doses of opium and cocaine. Gastric disturbances must be treated by the ordinary means according to their origin, and it should not be forgotten that patients suffering from diabetes are very liable to neuroses of the digestive system. The diabetic always suffers more or less from nervous disturbances. Neuralgic affections of the different nerves, partial paralysis, anæsthetic and hyperæsthetic areas, spasms, etc., occur often and baffle medical ingenuity.

Cutaneous diseases are also very frequent and equally obstinate; pathologically considered, those diseases of the skin which are of an acknowledged neurotic origin, such as zoster, urticaria and pruritus occur most frequently in diabetes. Furunculosis is also a very frequent accompaniment of diabetes; the sulphide of calcium in rapidly increasing doses has proved most successful in this complication. Preventive treatment, however, is the most effective and therefore the diabetic should not neglect those hygienic measures which pertain to the skin.

Much has been said about the use of the alkalines in this disease and much good has been reported from it. The mineral waters of Carlsbad, where the treatment of diabetes is carried on in a very large way, are especially vaunted for their efficacy. The activity of the alkalies, however, seems to be limited to the cases characterized by obesity, plethora, and gouty symptoms and it is mainly through this class of patients that Carlsbad has obtained its great reputation. The use of the sprudel coupled with the strictest injunction regarding diet, in connection with the change of surroundings and different mode of life, does not fail to benefit the cases mentioned.

In the severe form, where sugar is formed continually in spite of rigid albuminoid diet, it would be folly to resort to such active medication. Cod liver oil, a diet containing a moderation of starchy food, in conjunction with tonics suitable to the case and proper hygienic measures will then be of undoubted benefit.

When coma has supervened therapeutic measures are of almost no avail; the cases in which a successful result was had, are few. Saline enemas, intravenous injections of warm normal salt solution or of a 3 per cent. bicarbonate soda solution, transfusion of blood, all the ordinary stimulants such as ammonia or alcohol, are recommended from various sources and success is claimed. Inhalations of oxygen have also been given. Schmitz, of Neusnahr recommends large doses of castor oil, with the purpose of bringing about quick and copious evacuations, as he thinks that decomposition of the intestinal contents has much to do with the cause of the coma. It has been objected to this procedure, that on the other hand, it is often noticed that comatose diabetics could not retain their fæces and still perished. This latter might, however, be also construed as an unsuccessful effort of the vis medicatrix naturæ. Anyway the suggestion deserves a trial from its very simplicity and the hopelessness of other measures.

---

### Don't.

Don't fancy that you are insulted, or that there is a conspiracy against you, because your articles come back. It is a physical impossibility to print more than a very small percentage of those that are offered.

Don't overwork the useful word and. Once is often enough for it to appear in a sentence, as a rule. When you see it staggering from fatigue, take it out of the ranks, put a period in its place, and begin the next word with a capital.

# COMMUNICATIONS.

## PELVIC INFLAMMATION.*

J. C. SEXTON, Rushville, Ind.

Pelvic inflammations in women are so common, so painful, so dangerous, so persistent, so often incurable, so continually destructive, so frequently overlooked, so often negligently treated in the early stages; that a discussion of the subject cannot fail to be of benefit to us.

In presenting a paper the author writes either "from experience" or "for experience." The young docter writing "for experience" is often the subject of some little contempt on part of older and more experienced readers. But in writing for a society "for experience" may be of just as much value as "from experience." I come before you to-day to get the benefit of your views upon the topic just stated. Let us have the experience here to-day of the general practitioner. I write for his experience; how he observes these cases, how frequently, traces them to what causes, what methods of diagnosis, what plans of treatment he employs, how successful is he. I earnestly call upon him to give us the benefit of his work and of his study and observation. I write to-day for the experience of the physician-gynecologist, will he teach us of the cases he has watched and I trust faithfully recorded.

Of the surgeon-gynecologist let us be informed of what he finds and how he finds it. Will he not tell us his views from the store of his knowledge in dealing with the results of inflammation of pelvic organs. Of the ravages produced, of the destruction, and may we not expect that his work may be helpful in showing how such conditions may be avoided and such danger averted. Certainly an interchange of views will be of benefit and with this plea I submit a little of my own experience and ask yours in return.

When speaking of pelvic inflammation our ideas may be somewhat confused. Under the guide of former teachers many doubts arose as to the nature and results of pelvic diseases. To-day pelvic inflammation is only another expression for inflammation of the ovaries and tubes, for upon the health of these organs depends the health of the patient, and what damage will be wrought to these organs is the constant anxiety of the physician. Pelvic peritonitis indeed we might say is almost all that we to-day consider is our study of pelvic inflammation. Hence we speak almost synonymously of pelvic peritonitis, tubal disease, inflammation of tubes and ovaries, and disease of the appendages.

We have long ago left behind the various designations of parametritis and perimetritis because they did not designate. So then when we come to consider the causes of pelvic inflammations we ask ourselves what are the things and circumstances that will produce dangerous and lasting injury to those essential, if not vital, organs.

Let me be not misunderstood, for I have not said there was no pelvic inflammation without involvement of these organs, but there is no pelvic inflammation without danger of these organs becoming involved and their delicate and proper function destroyed. Let us not say there is no pelvic cellulitis, but insist that it is far less common than pelvic peritonitis and is found uncomplicated with tubal disease very rarely.
